Preface

Thirteen years have elapsed since the publication of the fourth edition of this book. In the interim, a large number of books and atlases on the subject of cytopathology have been published. Some of these books are lavishly illustrated with color photographs and a few have benefited from an excellent layout. Therefore, a legitimate question may be asked—whether a new edition of an “older” book (so characterized by a young cytopathologist testifying in a court case) is justified.

The colossal effort involved in updating this book was undertaken not to produce an atlas or a synoptic book that may appeal to readers favoring easy fare, but to create a textbook that covers, in depth, the broad field of human pathology through the prism of cells and corresponding tissue lesions. This book reflects half a century of practical and research experience of the principal author, now assisted by a trusted friend and colleague, Dr. Myron R. Melamed.

In rewriting this book, particular attention has been devoted to the interpretation of the increasingly important aspirated cell samples, colloquially known as fine needle aspiration biopsies or FNAs. A book on this topic, by Koss, Woyke, and Olszewski, published in 1992 by Igaku-Shoin, is out of print and no longer available. In the previous editions of *Diagnostic Cytology*, the topic was treated as a single, very large chapter, originally written by the late Dr. Josef Zajicek and his associates from the Karolinska Hospital in Stockholm; it was updated in the fourth edition by this writer. As this fifth edition was being planned, it became paramount to expand the single chapter into a series of chapters, each addressing in depth the topics at hand. We were fortunate to secure the help of several distinguished colleagues whose names are listed as authors of their chapters. The chapters written by the principal author and editor of this book (LGK) carry no author's name. All the contributions were carefully reviewed and revised by the senior editor; thus, the blame for any insufficiencies falls on his shoulders. Inevitably, some duplications of information occurred and were not eliminated. It was interesting to see how different observers look at the same, or similar, issues from a different vantage point. Innovations in the practice of cytopathology and, when available, data on molecular biology and cytogenetics have been incorporated into the discussion of organs and organ systems. Therefore, it is hoped that the book will continue to fulfill its role as a source of knowledge and references of value to the cytopathologists, the cytopathologist-in-training, the practicing pathologists, the cytotechnologists, and even some basic science investigators who may be interested in the clinical approach to a discussion of human cells and tissues. With the exception of some irreplaceable black-and-white photographs or drawings, the book is illustrated in color.

Another aspect of cytopathology that has emerged in the 1990s, to the dismay of many, has been the legal responsibility that cytopathologists have to assume if a diagnostic verdict is alleged to have led to significant damage or sometimes even death of a patient. Although there

are many who are attempting to soften the blow to their egos and pockets of their insurance company by contriving complex defense maneuvers, the bottom line remains, as it has always been, that the patients come first and are entitled to competent services by laboratories. This has been one of the guiding principles in this new edition, wherein considerable attention has been devoted to avoidance of errors.

This book took over five years to complete. It is hoped that the readers will find it informative and useful. With the aging process taking its toll, it is unlikely that future editions of this book, if any, will be written or edited by the same authors.

> Front of Book > Preface to First Edition, 1961

Preface to First Edition, 1961

The concept of diagnostic cytology as presented in this work has been greatly influenced by the efforts of Dr. George N. Papanicolaou. His contributions to our knowledge of the cytologic presentation of cancer have changed the status of cytology from a largely theoretical field of knowledge to a widely accepted laboratory procedure.

In the present work the widely used expression "exfoliative cytology" has been replaced by "diagnostic cytology." The method is not based on examination of exfoliated cells alone; material may be also obtained from organs that do not yield any spontaneously exfoliating cells. Cytology has ceased to be an adjunct to other methods of diagnosis; rather, it has become a primary source of information in many fields of medicine, such as gynecology, urology, and thoracic surgery, to name only a few. It is our feeling that the pathologist competent in examination of cytologic preparations should not suggest the possibility of a diagnosis but must learn to establish a diagnosis, in much the same way as on examination of histologic evidence. A laboratory of diagnostic cytology should be operated on the same principles as a laboratory of surgical pathology.

The purpose of the authors in the present volume is to outline and explain the principles of diagnostic cytology for the use of practicing pathologists and others who may be interested in this challenging field. The authors hope that this book will fill a gap in the library of manuals on methods of laboratory diagnosis.

This book consists of two parts: the first has been devoted to a brief résumé of basic cytology and cytopathology, the second part to special diagnostic cytology of organs. Each organ or system has been treated as follows:

1. Normal histology and cytology
2. Benign cytopathologic aberrations
3. Cytopathology of cancer

In some instances additional subdivisions were required. The pathology and the cytology of the female genital tract have been discussed in a somewhat more detailed manner because of great current interest.

Throughout an attempt has been made to interpret the cellular alterations in terms of patterns of disease. A description of histologic changes therefore precedes or accompanies, whenever possible, the discussion of the cytologic patterns.

The practice of diagnostic cytology is very time-consuming, and much of the task of screening smears is usually delegated to lay screeners or cytotechnologists. The role of trained cytotechnologists cannot be emphasized sufficiently, and their skill is a tremendous asset to the pathologist, to the laboratory, and last, but not least, to the patient. Since it is hoped that this book will also help in teaching and training of cytotechnologists, certain basic concepts of

anatomy, histology, cytology, and tissue pathology have been included. To those among the readers who will find these passages cumbersome, the authors express their apologies. However, it was felt that the book would be of greater practical value if the entire field of human pathology on the cellular level were presented in as complete a manner as possible.

Among the numerous applications of cytologic technics, one stands out very clearly. It is the place of cytology in the detection and the diagnosis of early, clinically silent cancer of various organs, such as cervix uteri, endometrium, bronchus, bladder, stomach, etc. Cytology has been primarily responsible for our increasing but still fragmentary knowledge of this group of diseases. Therefore, special emphasis in this book has been placed on the histologic and cytologic presentation of early cancer.

Statistical data pertaining to the value of cytology as applied to various organs have been omitted except for statements emphasizing specific points. The authors are satisfied that in their hands the method has proved to be highly reliable and accurate, and there are also other laboratories where the same standards prevail. The concept of a "false negative" cytologic diagnosis is as absurd as the concept of a "false negative" biopsy. Cytology is no substitute for a tissue biopsy but may be made equally reliable, especially in situations where a biopsy is not contemplated or not possible. As in other forms of laboratory diagnosis, it is practically impossible to avoid all errors in cytologic findings by comparison with histologic sections and thorough follow-up of patients are among the surest methods to improve and polish one's knowledge and to avoid the pitfalls of cellular morphology.

It is apparent that it would be beyond the scope of any volume to attempt to illustrate all the variations of normal and abnormal cells; therefore, the authors consider illustrations merely as an aid in the interpretation of the written word. The photographs, prepared by one of us (GRD), are chiefly in black and white and are based largely on material from Cytology and Pathology Laboratories at Memorial Hospital. Except when noted, the cytologic material was stained by Papanicolaou's technic, and the histologic material with hematoxylin and eosin. Use of more color photography would have raised the price of the book to prohibitive levels. The beautiful color pictures in Papanicolaou's Atlas^{*} may be profitably consulted in conjunction with the present text.

Since this book has no precedent, undoubtedly there will be some errors of judgment and omission. The authors will be grateful for criticism and corrections from the readers.

Acknowledgments

Several people were either essential or very helpful during the preparation of this book. Without the help of my secretary, Ms. Cordelia Silvestri, this book could never have been completed. Besides her extraordinary secretarial talents, she kept me and all the other authors on a short leash, kept records (and copies) of all the manuscript pages, and of archives as they built up. I thank Dr. Myron (Mike) R. Melamed, who consented to be a coeditor of this book. We have been friends and colleagues for half a century, having met while serving in the U.S. Army during the Korean War. Besides writing or revising several chapters, Mike always found time to discuss various aspects of this book with me and the publishers. The many other contributors, authors and coauthors, listed in the opening pages of this book and again as authors of various chapters, were willing to complete and deliver their work on time and suffered in silence at the indignities heaped upon them by the senior editor in reference to their text and photographs.

At Montefiore Medical Center, besides Ms. Silvestri, Mr. Barry Mordin patiently executed many of the tables and digitized many illustrations and diagrams. My colleagues Drs. Antonio Cajigas, Magalis Vuolo, and Maja Oktay assisted in finding missing references and offered helpful comments. Dr. Victoria Saksenberg, a cytopathology fellow (2003-2004), reviewed several manuscripts and translated them from American to Queen's English. Several cytotechnologists, particularly Gina Spiewack, were always willing to look for unusual cells needed as illustrations. A very special and heartfelt thanks to my dear friend and colleague of many years, Dr. Klaus Schreiber, who was always helpful in selecting illustrative material to be incorporated into the book. He was also willing to patiently listen to conceptual or practical problems and helped to find solutions. I thank Dr. Diane Hamele-Bena, now at Columbia-Presbyterian Medical Center, who prepared the beautiful drawings for Chapter 28. Special thanks to two old friends of mine, Professors Claude Gompel of Brussels, Belgium, who contributed several drawings, and Stanislaw Woyke of Warsaw and Szczecin, Poland who, generously allowed the use of several photographs. The support of Dr. Michael Prystowsky, the Chairman of Pathology at Montefiore/Einstein, during the long gestational period of this book was very much appreciated.

To all of these people, my deepest thanks and gratitude.

> Front of Book > To the Readers

To the Readers

The magnification factors of the color photographs taken with objectives 10×, 20 or 25×, or 40× are not included in the legends. Only unusual magnifications, such as very low power, very high dry power (objectives 60-80×), and oil immersion are listed. Two families of stains were predominantly used: Papanicolaou stain for fixed smears and one of the hematologic stains (May-Grünwald-Giemsa or Diff-Quik) for aspiration smears. Tissue sections were generally stained with hematoxylin and eosin. Exceptions are noted.

1

Diagnostic Cytology: Its Origins and Principles

EARLY EVENTS: THE BIRTH OF MICROSCOPY AND CLINICAL CYTOLOGY

Diagnostic cytology is the culmination of several centuries of observations and research. Although it is beyond the scope of this overview to give a detailed account of the past events, the readers may find a brief summary of these developments of interest.

Although some cells can be seen with the naked eye, for example, birds' or reptiles' eggs, it was the invention of the microscope that led to the recognition that all living matter is composed of cells. The term **microscope** was proposed in 1624 by an Italian group of scientists, united at the Academia dei Licei in Florence. The group, among others, included the great astronomer, Galileo, who apparently was also a user of one of the first instruments of this kind (Purtle, 1974). The first microscopes of practical value were constructed in Italy and in Holland in the 17th century. The best instrument, constructed by the Dutchman, **Anthony van Leeuwenhoek (1632-1723)** allowed a magnification of $\times 275$. Leeuwenhoek reported on the miraculous world of microscopy in a series of letters to the Royal Society in London. His observations ranged from bacteria to spermatozoa. Interested readers will find illustrations of Leeuwenhoek's work and further comments on him and his contemporaries in the excellent book entitled *History of Clinical Cytology* by Grunze and Spriggs (1983). For nearly 2 centuries thereafter, these instruments were costly, very difficult to use and, therefore, accessible only to a very small, wealthy elite of interested scientists, most of whom were amateurs dabbling with microscopy as a diversion. Many of these microscopes were works of art (Fig. 1-1). Using one of these microscopes with a focusing adjustment, the Secretary of the Royal College in London, **Robert Hooke**, observed, in 1665, that corks and sponges were composed of little boxes that he called **cells** (from Latin, *cellula* = chamber) but the significance of this observation did not become apparent for almost 200 years. The great 17th century Italian anatomist, Malpighi, was also familiar with the microscope and is justly considered the creator of histology. The event that, in my judgment, proved to be decisive in better understanding of

P.4

cell and tissue structure in health and disease was the invention of achromatic lenses that allowed an undistorted view of microscopic images. In the 1820s, the construction of compound microscopes provided with such optics occurred nearly simultaneously in London (by Lister, the father of Lord Lister, the proponent of surgical antisepsis) and in Paris (by the family of opticians and microscope makers, named Chevalier). These microscopes, with many subsequent improvements, were easy to use, could be mass-produced at a reasonable price, and thus became available to a great many interested professional investigators, leading to a better understanding of cell structure and, indirectly, to an insight into the mechanisms of cell function and, hence, of life processes. Although, even in the age of molecular biology, much

remains to be discovered about the interplay of molecules leading to cell differentiation and function, some progress has been made (see Chaps. 3 and 7) and more can be expected in the years to come.

Figure 1-1 Two beautiful 17th century microscopes. (Courtesy of the Billing's Collection, Armed Forces Institute of Pathology, Washington, DC.)

Nearly all the microscopic observations during the first half of the 19th century were conducted on cells because the techniques of tissue processing for microscopic examination were very primitive. Early on, the investigators observed that animal cells from different organs varied in size and shape and that some were provided with specialized structures, such as cilia. Perhaps the most remarkable record of these observations was an atlas of microscopic images by a French microscopist, **André François Donné**, published in Paris in 1845. The atlas was the first book illustrated with actual photomicrographs of remarkable quality (Fig. 1-2), obtained by the newly described method of Daguerre. The observations by many early observers led to the classification of normal cells and, subsequently, tissues as the backbone of normal cytology and histology. In the middle of the 19th century, the pioneering German pathologist, **Rudolf Virchow**, postulated that each cell is derived from another cell (*omnis cellula a cellula*). This assumption, which repeatedly has been proved to be correct, implies that at some time in a very distant past, probably many million years ago, the first cell, the mother of all cells, came to exist. How this happened is not known and is the subject of ongoing investigations.

By the middle of the 19th century, several books on the use of the microscope in medicine became available. In the book, *The Microscope in its Applications to Practical Medicine*,

P.5

that appeared in two editions (1854 and 1858), **Lionel Beale** of London described the cells as

follows: "A cell consists of a perfectly closed sac containing certain contents. The most important structure within the cell wall, in most instances, is the nucleus, upon which the multiplication of the cell ... (and other functions) ... depend. It must be borne in mind, however, that in some cells, such as the human blood corpuscles (erythrocytes, comment by LGK) a nucleus is not to be demonstrated. Within the nucleus there usually exists ... a clear bright spot. This is the nucleolus." Beale further classified cells into several categories according to their shapes (*scaly or squamous cells, tessellated cells* [epithelial cells lining serous membranes, LGK], polygonal cells, columnar cells, spherical cells, spindle-shaped cells, fusiform cells, etc.), thus describing the entire spectrum of cell configuration. He further described cells derived from various organs (including the central nervous system) and reported that some cells were ciliated, notably those of the trachea, bronchus, fallopian tubes and portions of the endocervical canal. Beale also reported that "some cells have a remarkable power of multiplication ... distinguished for the distinctness and number of its nuclei" (cancer cells). Beale described the use of the microscope to identify cancer of various organs that he could distinguish from a benign change of a similar clinical appearance. It is evident, therefore, that by the middle of the 19th century, approximately 150 years ago, there was considerable knowledge of the microscopic configuration of human cells and their role in the diagnosis of human disease.

Figure 1-2 Reproduction of Figure 33 from *Donné's Atlas*, published in 1845. The daguerreotype represents "vaginal secreta" and shows squamous cells, leukocytes, identified as "purulent globules" (b), and *Trichomonas vaginalis* (c). Note the remarkable pictorial quality of the unstained material.

Perhaps the most important series of observations pertinent to this narrative was the recognition that cells obtained from clinically evident cancerous growths differed from normal cells. The initial observations on cancer cells is attributed to a young German physiologist, **Johannes Müller**, who, in 1838, published an illustrated monograph entitled *On the Nature and Structural Characteristics of Cancer and Those Morbid Growth That Can Be Confounded With It*. In this monograph, Müller discussed at some length the differences in configuration of cells and their nuclei in cancer when compared with normal cells. Müller's original observations on the differences between normal and cancerous cells were confirmed by several investigators. For example, in 1860, Beale identified and described cancer cells in sputum. It may come as a surprise to some of the readers that as early as 1845 and 1851, a German microscopist, working in Switzerland and writing in French, **Hermann Lebert**, used cell samples aspirated from patients by means of a cannula for the diagnosis of cancer. In 1847, **M. Kün** of Strasbourg, about whom little is known, described a needle with a cutting edge useful in securing material from subcutaneous tumors, examined as smears (Grunze and Spriggs, 1983; Webb, 2001).

Virchow, often considered the father of contemporary pathology, and who was Müller's pupil, was a superb observer at the autopsy table and a good microscopist. He recognized and described the gross and microscopic features of a large number of entities, such as infarcts, inflammatory lesions, leukemia, and various forms of cancer. However, his views on the origin of human cancer were erroneous because he believed that all cancers were derived from connective tissue and not by transformation of normal tissues (Virchow, 1863). For this reason, he had difficulties in accepting the observations of two of his students and contemporaries, **Thiersch** in 1865 and **Waldayer** in 1867, who independently advocated the origin of carcinomas of the skin, breast, and uterus from transformed normal epithelium. Because Virchow wielded a tremendous influence in Germany, not only as a scientist but also as a politician (he was a Professor of Pathology in Berlin as well as a Deputy to the German Parliament, a socialist of sorts, who fought with the famous Chancellor, Bismarck), views that were in conflict with his own were often rejected, thus delaying the development of independent scientific thought. It took about 40 years until the confirmation of Thiersch's and Waldayer's concepts of the origin of carcinomas was documented by **Schauenstein** for the uterine cervix in 1908 (see Chap. 11). It took many more years until the concept of a preinvasive stage of invasive cancer, originally designated as *carcinoma in situ* by **Schottlander and Kermauner** in 1912, was generally accepted and put to a good clinical use in cancer detection and prevention.

These are but a few of the early contributions that have bearing on diagnostic cytology as it is known today. In addition to the contributors mentioned by name, there were many other heroes and antiheroes who made remarkable contributions to the science of human cytology during the second half of the 19th century, and this brief narrative doesn't do justice to them. The interested reader should consult a beautifully illustrated book on the history of clinical cytology by Grunze and Spriggs (1983).

Still, in spite of these remarkable developments, the widespread application of cytology to the diagnosis of human disease did not take place until the 1950s. Although

P.6

sporadic publications during the second half of the 19th century and the first half of the 20th century kept the idea of cytologic diagnosis alive, it was overshadowed by developments in histopathology.

THE ERA OF HISTOPATHOLOGY

The Beginning

Although cells teased from tissues were the main target of microscopic investigations during the first half of the 19th century, consistent efforts have been made to develop methods of tissue processing. Thus, in the 1858 edition of Beale's book, several pages are dedicated to the methods of hardening soft tissue samples by boiling and to the methods of preparation of transparent, thin sections suitable for microscopic examination with hand-held cutting instruments. Subsequently, various methods of tissue fixation were tried, such as chromium salts, alcohol, and ultimately, formalin and the manual cutting instruments were replaced by mechanical microtomes around 1880. Simultaneously, many methods of tissue staining were developed. There is excellent evidence that, by 1885, tissue embedding in wax or paraffin, cutting of sections with a microtome, and staining with hematoxylin and eosin were the standard methods in laboratories of pathology, as narrated in the history of surgical pathology at the Memorial Hospital for Cancer, now known as the Memorial Sloan-Kettering Cancer Center (Koss and Lieberman, 1997).

Two events enhanced the significance and value of tissue pathology. One was the introduction of the concept of a **tissue biopsy**, initially proposed for diagnosis of cancer of the uterine cervix and endometrium by **Ruge and Veit** in 1877, who documented that the microscope is superior to clinical judgment in the diagnosis of these diseases. However, the term **biopsy** is attributable to a French dermatopathologist, **Ernest Besnier**, who coined it in 1879 (Nezelof, 2000). The second event was the introduction of **frozen sections**, popularized by Cullen in 1895, which allowed a rapid processing of tissues and became an essential tool in guiding surgeons during surgery (see also Wright, 1985). With these two tools at hand, the study of cells was practically abandoned for nearly a century. Next to autopsy pathology, the mainstay of classification of disease processes during the 18th and 19th centuries, histopathology became the dominant diagnostic mode of human pathology, a position that it holds until today. Histopathology is based on **analysis of tissue patterns, which is a much simpler and easier task than the interpretation of smears that often requires tedious synthesis of the evidence dispersed on a slide**. Further, histopathology is superior to cytologic samples in determining the relationship of various tissues to each other, for example, in identifying invasion of a cancer into the underlying stroma.

Current Status

The introduction of histopathology on a large scale led to the rapid spread of this knowledge throughout Europe and the Americas. The ever-increasing number of trained people working in leading institutions of medical learning was capable of interpretation of tissue patterns supplementing clinical judgment with a secure microscopic diagnosis. Further, the tissue techniques allowed the preparation of multiple identical samples from the same block of tissue, thus facilitating exchanges between and among pathologists and laying down the **foundation of accurate classification of disease processes, staging and grading of cancers and systematic follow-up of patients, with similar disorders, leading to statistical behavioral studies of diseases of a similar type**. Such studies became of critical importance in evaluating treatment regimens, initially by surgery or radiotherapy and, even more so, after the introduction of powerful antibiotics and anti-cancer drugs that were active against diseases previously considered hopeless. Nearly all clinical treatment protocols are based on histologic

assessment of target lesions. Histologic techniques were also essential in **immunopathology** that allowed the testing of multiple antibodies on samples of the same tissue. Such studies are difficult to accomplish with smears, which are virtually always unique.

THE RETURN OF CYTOLOGY

Papanicolaou and the Cytology of the Female Genital Tract

The beginnings of the cytology of the female genital tract can be traced to the middle of the 19th century. The microscopic appearance of cells from the vagina was illustrated by several early observers, including Donné and Beale, whose work was discussed above (see Fig. 1-2). In 1847, a Frenchman, **F.A. Pouchet**, published a book dedicated to the microscopic study of vaginal secretions during the menstrual cycle. In the closing years of the 19th century, sporadic descriptions and illustrations of cancer cells derived from cancer of the uterine cervix were published (see Chap. 11).

However, there is no doubt whatsoever that the current resurgence of diagnostic cytology is the result of the achievements of **Dr. George N. Papanicolaou** (1883-1962), an American of Greek descent (Fig. 1-3). Dr. Pap, as he was generally known to his coworkers, friends, and his wife Mary, was an anatomist working at the Cornell University with a primary interest in endocrinology of the reproductive tract. Because of his interest in the menstrual cycle, he developed a small glass pipette that allowed him to obtain cell samples from the vagina of rodents. In smears, he could determine that, during the menstrual cycle, squamous cells derived from the vaginal epithelium of these animals followed a pattern of maturation and atrophy corresponding to maturation of ova. He made major contributions to the understanding of the hormonal mechanisms of ovulation and menstruation and is considered to be one of the pioneering contributors to reproductive endocrinology.

P.7

Figure 1-3 George N. Papanicolaou, 1954, in a photograph inscribed to the author.

However, his fame is based on an **incidental observation of cancer cells in vaginal smears of women** whose menstrual cycle he was studying. Papanicolaou had no training in pathology and it is, therefore, not likely that he himself identified the cells as cancerous. It is not known who helped Papanicolaou in the identification of cancer cells. It is probable that it was James Ewing who was at that time Chairman of Pathology at Cornell and who was thoroughly familiar with cancer cells as a consequence of his exposure to aspiration biopsies performed by the surgeon, Hayes Martin, at the Memorial Hospital for Cancer (see below). Papanicolaou's initial contribution to the subject of "New Cancer Diagnosis," presented during an obscure meeting on the subject of the Betterment of the Human Race in Battle Creek, MI, in May, 1928, failed to elicit any response. Only in 1939, prodded by Joseph Hinsey, the new Chairman of the Department of Anatomy at Cornell, had Papanicolaou started a systematic cooperation with a gynecologist, **Herbert Traut**, the Head of Gynecologic Oncology at Cornell, who provided him with vaginal smears on his patients. It soon became apparent that abnormal cells could be

found in several of these otherwise asymptomatic patients who were subsequently shown to harbor histologically confirmed carcinomas of **the cervix and the endometrium**.

Papanicolaou and Traut's article, published in 1941 and a book published in 1943, heralded a new era of application of cytologic techniques to a new target: the discovery of **occult** cancer of the uterus. Papanicolaou's name became enshrined in medical history by the term **Pap smear**, now attached to the cytologic procedure for cervical cancer detection. The stain, also invented by Papanicolaou and bearing his name, was nearly universally adopted in processing cervicovaginal smears.

Papanicolaou's name was submitted twice to the Nobel Committee in Stockholm as a candidate for the Nobel Award in Medicine. Unfortunately, he was not selected. As a member of the jury told me (LGK) many years later, the negative decision was based on the fact that Papanicolaou had never acknowledged previous contributions of a Romanian pathologist, **Aureli Babés** (Fig. 1-4), who, working with the gynecologist C. Daniel, reported in January 1927 that cervical smears, obtained by means of a bacteriologic loop, fixed with methanol and stained with Giemsa, were an accurate and reliable method of diagnosing cancer of the uterine cervix. On April 11, 1928, Babés published an extensive, beautifully illustrated article on this subject in the French publication, *Presse Médicale*, which apparently had remained unknown to Papanicolaou. One of the highlights

P.8

of Babés' article was the observation that a **cytologic sample may serve to recognize cancer of the uterine cervix before invasion**. Babés' observations were confirmed only once, by an Italian gynecologist, Odorico Viana in 1928, whereas Papanicolaou's work stimulated a large number of publications and received wide publicity. Both Babés' and Viana's articles were translated into English by Larry Douglass (1967 and 1970).

Figure 1-4 Aureli Babés. (Courtesy of Dr. Bernard Naylor, Ann Arbor, MI.)

The reason for Papanicolaou's success and Babés' failure to attract international attention clearly lies in the differences in geographic location (New York City vs. Bucharest) and in timing. If Papanicolaou's 1928 article were his only publication on the subject of cytologic diagnosis of cancer, he would have probably remained obscure. He had the great fortune to publish again in the 1940s and his ideas were slowly accepted after the end of World War II, with extensive help from Dr. Charles Cameron, the first Medical and Scientific Director of the American Cancer Society, which popularized the Pap test. A summary of these events was presented at a meeting of the American Cancer Society (Koss, 1993).

The Pap Smear: The Beginning

The value of the **vaginal smear** as a tool in the recognition of occult cancers of the uterine cervix and the endometrium was rapidly confirmed in a number of articles published in the 1940s (Meigs et al, 1943 and 1945; Ayre, 1944; Jones et al, 1945; Fremont-Smith et al, 1947).

It soon became apparent that the vaginal smear was more efficient in the discovery of cervical rather than endometrial cancer and the focus of subsequent investigations shifted to the uterine cervix. In 1948, **Lombard et al** from Boston introduced the concept of the vaginal smear as a screening test for cancer of the uterine cervix.

Because the vaginal smear was very tedious to screen and evaluate, the proposal by a Canadian gynecologist, **J. Ernest Ayre**, to supplement or replace it with a cell sample obtained directly from the uterine cervix under visual control was rapidly and widely accepted. In 1947, Ayre ingeniously proposed that a common wooden tongue depressor could be cut with scissors to fit the contour of the cervix, thus adding a very inexpensive tool that significantly improved the yield of cells in the cervical sample. **Ayre's scraper or spatula**, now made of plastic, has remained an important instrument in cervical cancer detection.

In 1948, the American Cancer Society organized a national conference in Boston to reach a consensus on screening for cervical cancer. The method was enthusiastically endorsed by the gynecologists but met with skepticism on the part of the participating pathologists. Nonetheless, the first recommendations of the American Cancer Society pertaining to screening for cervical cancer were issued shortly thereafter. In 1950, **Nieburgs and Pund** published the first results of screening of 10,000 women for occult cancer of the cervix, reporting that unsuspected cancers were detected in a substantial number of screened women. This seminal article, followed by a number of other publications, established the Pap test as a standard health service procedure. Further support for the significance of the test was a series of observations that the smear technique was helpful in discovering precancerous lesions (initially collectively designated as **carcinoma in situ**), which could be easily treated, thus preventing the development of invasive cancer.

Unfortunately, no double-blind studies of the efficacy of the cervicovaginal smear have ever been conducted, and it became the general assumption that the test had a very high specificity and sensitivity. The legal consequences of this omission became apparent 40 years later.

The Pap Smear From the 1950 to the 1980s

Although the American pathologists, with a few notable exceptions (Reagan, 1951), were reluctant to acknowledge the value of the cervicovaginal smear, toward the end of the 1960s, an ever-increasing number of hospital laboratories were forced to process Pap smears at the request of the gynecologists. In those years, the number of pathologists trained in the interpretation of cytologic material was very small, and it remained so for many years. The responsibility for screening and, usually the interpretation of the smears, was assumed by cytotechnologists who, although few in number, were better trained to perform this function than their medical supervisors. With the support of the National Cancer Institute, several schools for training of cytotechnologists were established in the United States in the 1960s. These trained professionals played a key role in the practice of cytopathology. This time period has also seen the opening of several large commercial laboratories dedicated to the processing of cervicovaginal smears. New books, journals, and postgraduate courses offered by a number of professional organizations gave the pathologists an opportunity to improve their skills in this difficult field of diagnosis.

Several very successful programs of cervix cancer detection were established in the United States and Canada, and it became quite apparent that the mortality from cancer of the uterine cervix could be lowered in the screened populations. As a consequence, by the end of the

1980s, a **70% reduction in the mortality** from this disease was recorded in several geographic areas where mass screening was introduced. **However, in none of the populations screened was cancer of the cervix completely eradicated.**

The Pap Smear From the 1980s to Today

In the 1970s and early 1980s, several articles commenting on the failure of the cervicovaginal smear in preventing the developments of invasive cancer of the uterine cervix appeared in the American literature and in Sweden (Rylander, 1976; Fetherstone, 1983; Koss, 1989; summary in Koss and Gompel, 1999). The reports did not fully analyze the reasons for failure and were generally ignored. In 1987, however, an article in the *Wall Street Journal* by an investigative journalist, **Walt Bogdanich**, on failure of laboratories to identify cancer of the cervix in young women, some who were mothers of small children, elicited a great deal of attention. It prompted the Congress of the United States in 1988 to promulgate a law, known as the Amendment to the Clinical

P.9

Laboratory Improvement Act (**CLIA 88**), governing the practice of gynecologic cytology in the United States. The implications of the law in reference to practice of cytopathology are discussed elsewhere in this book (see Chap. 44). Suffice it to say, cytopathology, particularly in reference to cervicovaginal smears, has become the object of intense scrutiny and legal proceedings against pathologists and laboratories for alleged failure to interpret the smears correctly, casting a deep shadow on this otherwise very successful laboratory test.

As a consequence of these events, several manufacturers have proposed changes in collection and processing of the cervicovaginal smears. The collection methods of cervical material in **liquid media**, followed by automated processing with resulting “**monolayer**” preparations, have been approved by the Food and Drug Administration (USA). Other manufacturers introduced apparatuses for automated screening of conventional smears. New **sampling instruments** were also developed and widely marketed, notably endocervical brushes. All these initiatives were designed to reduce the risk of errors in the screening and interpretation of cervicovaginal smears. These issues are discussed in Chapters 8, 11, 12, and 44.

DEVELOPMENTS IN NONGYNECOLOGIC CYTOLOGY

Historical Overview

At the time of early developments in general cytology in the 19th century, summarized above, numerous articles were published describing the application of cytologic techniques to various secretions and fluids, such as sputum, urine, effusions, and even vomit for diagnostic purposes. These contributions have been described in detail in Grunze and Spriggs' book. The recognition of lung cancer cells in sputum by **Beale** in 1858 was mentioned above.

As lung cancer became a serious public health dilemma in the 1930s and 1940s, in **Great Britain**, **Dudgeon and Wrigley** developed, in 1935, a method of “wet” processing of smears of fresh sputum for the diagnosis of lung cancer. The method was used by **Wandall** in Denmark in 1944 on a large number of patients, with excellent diagnostic results. Woolner and McDonald (1949) at the Mayo Clinic and Herbut and Clerf (1946) in Philadelphia also studied the applications of cytology to lung cancer diagnosis. In the late 1940s and early 1950s, Papanicolaou, with several co-workers, published a number of articles on the application of cytologic techniques to the diagnosis of cancer of various organs, illustrated in his Atlas. In the United Kingdom, urine cytology was applied by **Crabbe** (1952) to screening of industrial

workers for cancer of the bladder and gastric lavage techniques by **Schade** (1956) to screening for occult gastric cancer, a method extensively used in Japan for population screening. Esophageal balloon technique was applied on a large scale in China for detecting precursor lesions of esophageal carcinoma. Screening for oral cancer has been shown to be successful in discovering occult carcinomas in situ. **Thus, conventional cytologic techniques, when judiciously applied, supplement surgical pathology in many situations when a tissue biopsy is either not contemplated, indicated, or not feasible.** It needs to be stressed that cytopathology has made major contributions to the recognition of early stages of human cancer in many organs and, thus, contributed in a remarkable way to a better understanding of events in human carcinogenesis and to preventive health care. These, and many other applications of cytologic techniques to the diagnosis of early and advanced cancer and of infectious disorders of various organs, are discussed in this text.

THE ASPIRATION BIOPSY (FNA)

The Beginning

Ever since syringes or equivalent instruments were introduced into the medical armamentarium, probably in the 15th century of our era, they were used to aspirate collections of fluids. With the introduction of achromatic microscopes and their industrial production in the 1830s, the instrument became accessible to many observers who used it to examine the aspirated material. It has been mentioned above that a French physician, **Kün**, and a German-Swiss pathologist, **Lebert**, described, in 1847 and 1851, the use of a cannula to secure cell samples from palpable tumors and used the microscope to identify cancer. Sporadic use of aspirated samples has been described in the literature of the second half of the 19th century and in the first years of the 20th century. An important contribution was published in 1905 by two British military surgeons, **Greig and Gray**, working in Uganda who aspirated the swollen lymph nodes, by means of a needle and a syringe, of patients with sleeping sickness to identify the mobile trypanosoma (see Webb, 2001 for an excellent recent account of early investigators).

In the 20th century, to my knowledge, the first aspiration biopsy diagnosis of a solid tumor of the skin (apparently a lymphoma) was published by **Hirschfeld** (1912), who was the first person to use a **small-caliber needle**. He subsequently extended his experience to other tumors, but was prevented by World War I from publishing his results until 1919. Several other early observers reported on the aspiration of lymph nodes and other accessible sites (Webb, 2001).

The most notable development in diagnostic aspiration biopsy was a paradoxical event. **James Ewing**, the Director of the Memorial Hospital for Cancer in New York City and also a Professor of Pathology at Cornell University Medical School, was a dominant figure in American oncologic pathology between 1910 and 1940. Although Ewing has made great contributions to the classification and identification of human cancer, he was adamantly opposed to tissue biopsies because they allegedly contributed to the spread of cancer (Koss and Lieberman, 1997). Because of the ban on tissue biopsies, a young surgeon and radiotherapist at the Memorial Hospital, **Hayes Martin**, who refused to treat patients

P.10

without a preoperative diagnosis, began to aspirate palpable tumors of various organs by means of a large-caliber needle and a Record syringe. The material was prepared in the form of air-dried smears, stained with hematoxylin and eosin by Ewing's technician, **Edward Ellis**. Tissue fragments (named *clots*) were embedded in paraffin and processed as cell blocks.

Palpable lesions of lymph nodes, breast, and thyroid were the initial targets of aspiration. The material was interpreted by Ewing's associate and subsequent successor (and my Chief-LGK), **Dr. Fred W. Stewart**. In response to a specific query, the reasons for this development were explained many years later in a letter dated June 30, 1980, written by Dr. Fred W. Stewart to this writer.

Martin and Ewing were at sword's point on the need for biopsy proof prior to aggressive surgery or radiation (in neck nodes since Hayes Martin dealt exclusively in head and neck stuff) and the needle was a sort of compromise. Ewing thought biopsy hazardous—a method of disease spread. The material was seen mostly by me (FWS). Ewing, at the time, was quite inactive. Eddie Ellis merely fixed and stained the slides. He probably looked at them—he was used to looking at stuff with Ewing and really knew more about diagnoses than a lot of pathologists of the period. The needle really spread from neck nodes to the various other regions, especially to the breast, of course.

The method proved to be very successful and accurate with very few errors or clinical complications. Martin and Ellis published their initial results in 1930 and 1934. In 1933, Dr. Fred W. Stewart published a classic article, “The Diagnosis of Tumors by Aspiration,” in which he discussed, at length, the pros and cons of this method of diagnosis, its achievements, and pitfalls, based on experience with several hundred samples. As Stewart himself stated in a letter (to LGK), he was “damned by many for having advocated this insecure and potentially harmful method of diagnosis, without a shred of proof.” For a detailed description of these events, see Koss and Lieberman (1997). In fact, the method of aspiration pioneered by Martin has remained a standard diagnostic procedure at Memorial Sloan-Kettering Cancer Center until today (2004), the only institution in the world where the procedure has remained in constant use for more than 75 years. There is no evidence that the Memorial style aspiration smear was practiced on a large scale anywhere else in the world. The method was described and illustrated by John Godwin (1956) and again in the first edition of this book (1961) by John Berg, but has met with total indifference in the United States.

In Europe, on the other hand, the interest in the method persisted. Thus, in the 1940s, two internists, **Paul Lopes-Cardozo** in Holland and **Nils Söderström** in Sweden, experimented on a large scale with this system of diagnosis, using **small-caliber needles and hematologic techniques** to process the smears. **Lopes-Cardozo and Söderström** subsequently published books on the subject of thin-needle aspiration. Although both books were published in English, they had virtually no impact on the American diagnostic scene, but were widely read in Europe.

Current Status

Working at the Radiumhemmet, the Stockholm Cancer Center, the radiotherapist-oncologist, **Sixten Franzén**, and his student and colleague, **Josef Zajicek**, applied the thinneedle technique first to the prostate and, subsequently, to a broad variety of targets, ranging from lesions of salivary glands to the skeleton. Franzén et al (1960) described a syringe (initially developed for the diagnosis of prostatic carcinoma) that allowed performance of the aspiration with one hand, whereas the other hand steadied the target lesion (see Chap. 28). As nonpathologists, these observers used air-dried smears, stained with hematologic stains. In the 1970s, special aspiration biopsy clinics were established in Stockholm and elsewhere in Sweden to which patients with palpable lesions were referred for diagnosis. The technique soon became an acceptable substitute for tissue biopsies. An extensive bibliography, generated by the Swedish group, supported the value and accuracy of the procedure (Zajicek, 1974,

1979; Esposti et al, 1968; Löwhagen and Willems, 1981).

It can be debated why the aspiration biopsy flourished in Sweden, whereas initially it was unequivocally rejected in the United States (see Fox, 1979). This writer believes that the Swedish success was caused, in part, by inadequate services in biopsy pathology because, by tradition, in the academic Departments of Pathology (that are the mainstay of Swedish pathology), research took precedence over services to patients, a situation quite different from that in the United States (see exchange of correspondence between Koss, 1980, and Söderström, 1980). A further reason for the Swedish success was the government-sponsored health system, based on salaries, which offered no monetary rewards to surgeons and other clinicians for the performance of biopsies. Therefore, the creation of aspiration diagnostic centers offering credible and rapid diagnoses was greeted with enthusiasm. This is yet another major point of difference with the situation in the United States, where surgeons (and sometimes other specialists) feel financially threatened if the biopsies are performed by people encroaching on their "turf."

Although the Swedish authors published in English and also contributed to this book (editions 2, 3, and 4), the impact of thin-needle aspiration techniques on the American scene initially has been trivial and confined to a few institutions and individuals. The radical change in attitude and the acceptance of the cytologic aspirates in the United States may be due to several factors. Broad acceptance of exfoliative cytologic techniques (Pap smears) for detection and diagnosis of cervix cancer, subsequently extended to many other organs, clearly played a major role in these developments. The introduction of new imaging techniques, such as imaging with contrast media, computed tomography, and ultrasound, not only contributed to improved visualization of organs but also to **roentgenologists' ability to perform a number of diagnostic procedures by aspiration of visualized lesions**, hitherto in the domain of surgeons (Ferucci, 1981; Zornoza, 1981; Kamholz et al, 1982). After timid beginnings in the early 1970s, documenting

P.11

that the use of a thin needle was an essentially harmless and diagnostically beneficial procedure, a new era of diagnosis began which initially forced the pathologists to accept the cytologic sample as clinically valid and important. In those days, most pathologists had to struggle to interpret such samples. Thus, once again, the pathologists were forced into an area of morphologic diagnosis for which they were not prepared by training or experience.

The current enthusiasm for this method in the United States is surely related to the Swedish experience that insisted that the **interpreter of the smears (i.e., the cytopathologist) should also be the person obtaining cell samples of palpable lesions directly from patients**. In fact, many of the leaders in this field were trained in Sweden, particularly by the late Dr. **Torsten Löwhagen**. This was the exact opposite of the situation in the 1960s, when Swedish observers repeatedly visited the Memorial Hospital for Cancer in New York City to learn the secrets of the aspiration biopsy. Nowadays, by performing the procedure and by interpreting its results, the pathologists assume an important role in patient care. Without much doubt, **aspiration cytology has become an elixir of youth for American pathology**, making those who practice it into clinicians dealing with patients, not unlike the pioneers of pathology in the 19th century.

At the time of this writing (2004), biopsy by aspiration, also known as **thin- or fine-needle aspiration biopsy (FNA)**, has become an important diagnostic technique, sometimes replacing but often complementing tissue pathology in many clinical situations. The targets of the

aspiration biopsy now **encompassed virtually all organs of the human body**, as discussed in Chapter 28 and subsequent chapters. Within recent years, numerous books, many lavishly illustrated, have been published on various aspects of aspiration cytology. With a few exceptions, these books do not address the key issue of the aspiration biopsy: it is a **form of surgical pathology, practiced on cytologic samples** (Koss, 1988). Only those who have expertise in tissue pathology are fully qualified to interpret the aspirated samples without endangering the patient. These aspects of aspiration cytology are discussed in Chapter 28.

Figure 1-5 Exfoliative cytology. A schematic representation of the cross section of the vagina, uterine cervix, and the lower segment of the endometrial cavity. Cells desquamating from the epithelial lining of the various organs indicated in the drawing accumulate in the posterior vaginal fornix. Thus, material aspirated from the vaginal fornix will contain cells derived from the vagina, cervix, endometrium, and sometimes fallopian tube, ovary, and peritoneum. Common components of vaginal smears include inflammatory cells, bacteria, fungi, and parasites such as *Trichomonas vaginalis* (see Fig. 1-2). Red indicates squamous epithelium, blue represents endocervical epithelium, and green is endometrium.

CYTOLOGIC SAMPLING TECHNIQUES

Diagnostic cytology is based on **four basic sampling techniques**:

- **Collection of exfoliated cells**
- **Collection of cells removed by brushing or similar abrasive techniques**
- **Aspiration biopsy (FNA) or removal of cells from palpable or deeply seated lesions by means of a needle, with or without a syringe. Aspiration biopsy (FNA) procedures are described in Chapter 19 for lung and pleura and Chapter 28 and subsequent chapters for all other organs.**
- **Intraoperative cytology (see below)**

Exfoliative Cytology

Exfoliative cytology is based on spontaneous shedding of cells derived from the lining of an organ into a body cavity, whence they can be removed by nonabrasive means. Shedding of cells is a phenomenon based on constant renewal of an organ's epithelial lining. Within the sample, the age of these cells cannot be determined: some cells may have been shed recently,

others may have been shed days or even weeks before. A typical example is the **vaginal smear** prepared from cells removed from the posterior fornix of the vagina. The cells that accumulate in the vaginal fornix are derived from several sources: the squamous epithelium that lines the vagina and the vaginal portio of the uterine cervix, the epithelial lining of the endocervical canal, and other sources such as the endometrium, tube, the peritoneum, and even more distant sites (Fig. 1-5). These cells accumulate in the mucoid material and other secretions from the uterus and the vagina. The vaginal smears often contain leukocytes and macrophages that may accumulate in response to an inflammatory process, and a variety of microorganisms such as bacteria, fungi, viruses, and parasites that may inhabit the lower genital tract.

Another example of exfoliative cytology is the **sputum**. The sputum is a collection of mucoid material that contains cells derived from the buccal cavity, the pharynx, larynx,

P.12

and trachea, the bronchial tree and the pulmonary alveoli, as well as inflammatory cells, microorganisms, foreign material, etc. The same principle applies to **voided urine** and to a variety of **body fluids (effusions)**. The principal targets of exfoliative cytology are listed in Table 1-1.

It is evident from these examples that a cytologic sample based on the principle of exfoliated cytology will be characterized by a great variety of cell types, derived from several sources. An important feature of exfoliative cytology is the poor preservation of some types of cells. Depending on type and origin, some cells, such as squamous cells, may remain relatively well preserved and resist deterioration, whereas other cells, such as glandular cells or leukocytes, may deteriorate and their morphologic features may be distorted, unless fixed rapidly. In addition, spontaneous cleansing processes that naturally occur in body cavities may take their toll. Most cleansing functions are vested in families of cells known as *macrophages* or *histiocytes* and *leukocytes*. These cells may either phagocytize the deteriorating cells or destroy them with specific enzymes (see Chap. 5). A summary of principal features of exfoliative cytology is shown in Table 1-2. The exfoliated material is usually examined in smears, filters, and cell blocks or by one of the newer techniques of preservation in liquid media and machine processing (see below).

Abrasive Cytology

In the late 1940s and 1950s, several new methods of securing cytologic material from various body sites were developed. The purpose of these procedures was to enrich the sample with cells obtained directly from the surface of the target organ. The **cervical scraper or spatula**, introduced by Ayre in 1947, allowed a direct sampling of cells from the squamous epithelium of the uterine cervix and the adjacent endocervical canal (Fig. 1-6). A **gastric balloon** with an abrasive surface, developed by Panico et al (1950), led to the development of devices known as **esophageal balloons**, extensively used in China for the detection of occult carcinoma of the esophagus in high-risk areas (see Chap. 24). A number of **brushing instruments**, suitable for sampling

P.13

various organs, were also developed (see below). Several such instruments were developed for the sampling of the uterine cervix (see Fig. 8-45).

TABLE 1-1 PRINCIPAL TARGETS OF EXFOLIATIVE CYTOLOGY

Target Organ	Techniques*	Principal Lesions To Be Identified	Incidental Benefits
Female genital tract	Smear of material from the vaginal pool obtained by pipette or a dull instrument. Fixation in alcohol or by spray fixative.	Precancerous lesions and cancer of the vagina, uterine cervix, endometrium, rarely fallopian tubes, ovaries	Identification of infectious agents, such as bacteria, viruses, fungi, or parasites (Chapters 8, 9, 10, 11, 12, 13, 14, 15, 16, 17 and 18)
Respiratory tract	Sputum: either fresh or collected in fixative (smears and cell blocks)	Precancerous states mainly carcinoma in situ and lung cancers	Identification of infectious agents, such as bacteria, viruses, fungi, or parasites (Chapters 19 and 20)
Urinary tract	Voided urine; fresh or collected in fixative (smears and cytocentrifuge preparations)	Precancerous states, mainly flat carcinoma in situ and high grade cancers	Identification of viral infections and effect of drugs (Chapters 22 and 23)
Effusions (pleural, peritoneal, or pericardial)	Collection of fluid: fresh or in fixative (smears and cell blocks)	Metastatic cancer and primary mesotheliomas	(Chapters 25 and 26)
Other fluids (cerebrospinal fluid, synovial fluid, etc.)	Collection in fixative Cytocentrifuge preparations	Differential diagnosis between inflammatory processes and metastatic cancer	Identification of infectious agents (viruses, fungi) (Chapter 27)

* For further details of sample collection see this and other appropriate chapters. For further technical details, see Chapter 44.

TABLE 1-2 PRINCIPAL FEATURES OF EXFOLIATIVE CYTOLOGY

- The technique is applicable to organs with easy clinical access whence the samples can be obtained.
- The samples often contain a great variety of cells of various types from many different sources.
- The cellular constituents are sometimes poorly preserved.
- The samples may contain inflammatory cells, macrophages, microorganisms, and material of extraneous origin.
- The signal advantage of exfoliative cytology is the facility with which multiple samples can be obtained.

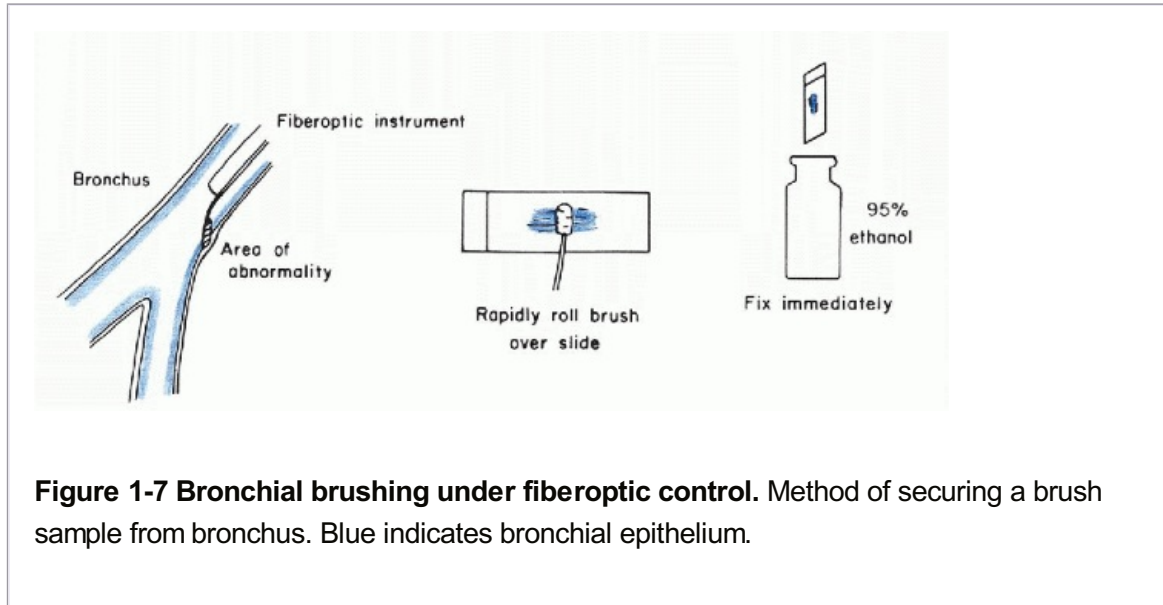

Figure 1-6 Method of obtaining an abrasive sample (scraping) from the uterine cervix by means of Ayre's scraper. Red indicates squamous epithelium and blue indicates endocervical mucosa.

Endoscopic Instruments

The developments in optics led to the introduction of rigid endoscopic instruments for the inspection of hollow organs in the 1930s and 1940s. Bronchoscopy, esophagoscopy, and sigmoidoscopy were some of the widely used procedures. In the 1960s, **new methods of endoscopy** were developed based upon transmission of light along flexible glass fibers. This development led to the construction of flexible, **fiberoptic instruments** permitting visual inspection of viscera of small caliber or complex configuration, such as the secondary bronchi or the distal parts of the colon, previously not accessible to rigid instruments. The fiberoptic instruments are provided with small brushes, biopsy forceps, or needles that permitted a very precise removal of cytologic samples or small biopsies.

The introduction of fiberoptic instruments **revolutionized the cytologic sampling of organs of the respiratory and gastrointestinal tracts** and, to a lesser extent, the urinary tract. The brushes could be used under direct visual control for sampling of specific lesions or areas that were either suspect or showed only slight abnormalities (Fig 1-7). The method became of major importance in the search for early cancer of the bronchi (including carcinoma in situ) and of

superficial cancer of the esophagus and stomach (see Chaps. 20 and 24). Transbronchial aspiration biopsies of submucosal lesions could also be performed. The introduction of fiberoptic sigmoidoscopes and colonoscopes contributed to a better assessment of abnormalities that were either detected by roentgenologic examination or were unsuspected. Colonic brush cytology proved to be useful in searching for recurrences of treated carcinoma or in the search for early carcinoma in patients with ulcerative colitis (see Chap. 24).

The cytologic samples obtained by brushings, with or without fiberoptic guidance, differ markedly from exfoliated samples. The cells are removed directly from the tissue of origin and, thus, do not show the changes caused by degeneration or necrosis. Inflammatory cells, if present, are derived from the lesion itself and are not the result of a secondary inflammatory event. The sample is usually scanty and careful technical preparation is required to preserve the cellular material. The methods of smear preparation are described in Chapters 8 and 44.

Since fiberoptic instruments can also be used for tissue biopsies of lesions that can be visualized, one must justifiably ask why cytologic techniques are even used. Experience has shown, however, that brush specimens result in sampling of a wider area than biopsies. This is occasionally of clinical value, particularly in the absence of a specific lesion. Brushing and aspiration techniques also allow the sampling of submucosal lesions. A summary of the principal features of abrasive cytology is shown in Table 1-3.

Washing or Lavage Techniques

Washing techniques were initially developed as a direct offshoot of rigid endoscopic instruments. On the assumption that cells could be removed from their setting and collected in lavage fluid from lesions not accessible or not visible to the endoscopist, small amounts of normal saline or a similar solution were instilled into the target organ under visual control, aspirated, and collected in a small container. A pioneering effort by Herbut and Clerf in Philadelphia (1946)

P.14

defined the technique of bronchial washings for the diagnosis of lung cancer. The esophagus, colon, bladder, and occasionally other organs were also sampled in a similar fashion (see corresponding chapters).

TABLE 1-3 PRINCIPAL FEATURES OF ABRASIVE CYTOLOGY

- The method allows direct sampling of specific targets, such as the surface of the uterine cervix or a bronchus.
- With the use of fiberoptic instruments direct samples of accessible internal organs may be secured.
- The cells obtained by abrasive techniques are derived directly from the tissue and thus are better preserved than exfoliated cells and require different criteria for interpretation.
- Subepithelial lesions may be sampled by brushing or aspiration techniques.
- Care must be exercised to obtain technically optimal preparations.

With the development of flexible fiberoptic instruments, brushings largely replaced the washing techniques. However, several new lavage techniques were developed. The three principal techniques are the **peritoneal lavage** (described in Chap. 16), **bronchoalveolar lavage** (described in Chap. 19), and **lavage or barbotage of the urinary bladder** (described in Chaps. 22 and 23).

Because relatively large amounts of fluid are collected during these procedures, the samples cannot be processed by a direct smear technique. The cells have to be concentrated by centrifugation, filtering, or cell block techniques described in Chapter 44.

The principal targets of abrasive cytology, washings, and lavage are shown in Table 1-4.

Body Fluids

The cytologic study of body fluids is one of the oldest applications of cytologic techniques, first investigated in the latter half of the 19th century. The purpose is to determine the cause of fluid accumulation in body cavities, such as the pleura, pericardium (effusions), and the abdominal cavity (ascitic fluid). Primary or metastatic cancer and many infectious processes can be so identified (see Chaps. 25 and 26).

Other applications of this technique pertain to cerebrospinal fluid and other miscellaneous fluids, described in Chapter 27. The cell content of the fluid samples must be concentrated by centrifugation, sedimentation, or filtration as described in Chapter 44. The material is processed as smears, filter preparations, or cell block techniques.

Aspiration Cytology (FNA)

The technical principles of aspiration cytology are discussed in Chapter 28. The technique of aspiration of the lung and mediastinum is discussed in Chapters 19 and 20. Organ-specific features are described in appropriate chapters. The principal features of the technique are summarized in Table 1-5.

Intraoperative Cytology

Intraoperative consultations by frozen sections are a very important aspect of practice in surgical pathology that is often guiding the surgeon's hand. Supplementing or replacing frozen sections by cytologic **touch, scrape, or crush preparations** has been in use in

neuropathology for many years (Eisenhardt and Cushing, 1930; McMenemey, 1960; Roessler et al, 2002) (see Chap. 42) and more recently has been receiving increased attention in other areas of pathology as well (summary in Silverberg, 1995).

Methods

The smears are prepared by forcefully pressing a clean glass slide to the cut surface of the tissue. Good smears may also be obtained by scraping the cut surface of the biopsy with a small clean scalpel and preparing a smear(s) from the removed material. Crushing small fragments of tissue between two slides and pulling them apart is particularly useful in assessing lesions of the central nervous system where obtaining large tissue samples for frozen sections may be technically difficult, but may also be applied to other organs.

As with aspiration biopsy samples, the smears may be air-dried and stained with a rapid hematologic stain or fixed and stained with either Papanicolaou or hematoxylin and eosin, depending on the preference and experience of the pathologist. These techniques are described in greater detail in Chapters 28 and 44.

Applications

Intraoperative cytology is applicable to all organs and tissues. As examples, biopsies of the breast (Esteban et al, 1987), parathyroid (Sasano et al, 1988), uterine cervix (Anaastasiadis et al, 2002), and many other tissue targets (Oneson et al, 1989) may be studied. Recently, several communications evaluated the results of cytologic evaluation of **sentinel lymph nodes** in breast cancer (Viale et al, 1999; Llatjos et al, 2002; Creager et al, 2002a) and malignant melanoma (Creager et al, 2002b).

Advantages and Disadvantages

When compared with a frozen section, the smears are much **easier, faster, and cheaper** to prepare. Thus, the principal value of intraoperative cytology is a **rapid diagnosis**. Intraoperative cytology is of special value if the tissue **sample is very small and brittle** (as biopsies of the central nervous system) but sometimes of other organs, such as the pancreas, that are not suitable for freezing and cutting (Kontozoglou and Cramer, 1991; Scucchi et al, 1997; Blumenfeld et al, 1998).

The **interpretation** of smears is **identical to** that of material obtained by **aspiration biopsy, discussed in appropriate chapters**. As is true with other cytologic preparations, the interpretation of intraoperative smears requires training and experience. However, even in experienced hands, a correct diagnosis may be difficult or impossible if the target tissue contains only very small foci of cancer, which can only be identified by special techniques such as immunocytochemistry, as is the case in some sentinel lymph nodes.

P.15

TABLE 1-4 PRINCIPAL TARGETS OF ABRASIVE CYTOLOGY WASHINGS AND LAVAGE TECHNIQUES			
Target Organ	Technique *	Principal Lesions to Be Identified	Incidental Benefits

Female Genital Tract

Uterine cervix, vagina, vulva, endometrium	Scrape or brush; smear with immediate fixation in alcohol or spray fixative	Precancerous states and early, cancer and their differential diagnosis	Cancerous processes in other organs or the female genital tract may be identified (ovary, tube); identification of infectious processes (Chapters 12, 14, and 16)
Peritoneal fluid collection and washings	Fluid sample: collect in fixative	Residual or recurrent cancer of ovary, tube, endometrium, or cervix	(Chapter 16)

Respiratory Tract

Bronchial brushing; bronchial washings and lavage; bronchoalveolar lavage	Identification of precancerous states, lung cancer, and infections	Recognition of infectious agents; chemical and immunologic analysis of fluids in chronic fibrosing lung disease (Chapters 19 and 20)
---	--	--

Buccal Cavity and Adjacent Organs

Direct scrape smear; fixation as above	Identification of precancerous states and cancer	(Chapter 21)
--	--	--------------

Urinary Tract

Bladder washings or barbotage; processed fresh or fixed	Identification of carcinoma in situ and related lesions	Monitoring of effect of treatment; DNA analysis by flow cytometry or image analysis (Chapter 23)
---	---	--

***Gastrointestinal
Tract***

Esophagus	Brush or balloon smears; fixation as above	Identification of precancerous states (mainly carcinoma in situ and dysplasia), early cancer, or recurrent cancer after treatment	} (Chapter 24)
Stomach	Brush, rarely balloon; smears, fixation as above		
Colon	Brush; smears, fixation as above	Monitoring of ulcerative colitis	
Bile ducts and pancreas	Aspiration of pancreatic juice (essentially obsolete); brushing	Diagnosis of cancer of the biliary tree and pancreas	

* Techniques of collection of cell samples in liquid media and processing by specially constructed machines or apparatuses are described in Chapter 44.

P.16

TABLE 1-5 PRINCIPAL FEATURES OF THIN-NEEDLE ASPIRATION BIOPSY

- Impeccable aspiration and sample preparation techniques are required for optimal results.*
- Virtually any organ in the body can be sampled using either palpation or imaging techniques.
- Thorough knowledge of surgical pathology is required for the interpretation of the sample.
- The technique is well tolerated, easily adaptable as an outpatient procedure, rapid, and cost-effective.

* See Ljung et al., 2001, and Chapter 28.

By nearly unanimous consensus of the authors of numerous articles on this topic, **false-positive cancer diagnoses are very rare in experienced hands** (specificity approaches 100%), but **failures to recognize a malignant tumor are not uncommon**. The **sensitivity** and overall accuracy of the method are approximately 80% to 85%.

Clearly, in many cases of cancer, the intraoperative cytology will obviate the need for frozen sections and will replace frozen sections in special situations.

Application of Cytologic Techniques at the Autopsy Table

It is gratifying that several observers proposed the use of **cytologic techniques at the autopsy table**, as first described by Suen et al in 1976. The technique, based on touch preparations or needle aspiration of visible lesions, offers the option of a **rapid preliminary diagnosis** that may be of value to the clinicians and pathologists. Further, this approach is an **excellent teaching tool** of value in training house officers in cytology. Ample evidence has been provided that this simple and economical technique should be extensively used (Walker and Going, 1994; Survarna and Start, 1995; Cina and Smialek, 1997; Dada and Ansari, 1997).

TELECYTOLOGY

New developments in microscopy, image analysis, and image transmission by microwaves, telephone, or the Internet have generated the possibility of exchange of microscopic material among laboratories and the option of consultations with a distant colleague. The concept was applied to histopathology (summary in Weinstein et al, 1996, 1997) and expanded to cytology (Raab et al, 1996; Briscoe et al, 2000; Allen et al, 2001; Alli et al, 2001).

As a **consultation system**, the method is particularly appealing for solo practitioners in remote areas who can benefit from another opinion offered by a large medical center in difficult cases. On an experimental basis, the system was applied to cervicovaginal smears (Raab et al, 1996), breast aspirates (Briscoe et al, 2000), and a variety of other types of specimens (Allen et al, 2001).

The accuracy of the system in reference to cervicovaginal smears was tested by Alli et al (2001) comparing the diagnoses established by several pathologists on glass slides and digital images. The diagnostic agreement in this study was low to moderate, although the levels of disagreement were relatively slight. Discrepancies were also reported in reference to other types of material (Allen et al, 2001).

Although theoretically very appealing and possibly useful in select situations such as the diagnosis of breast cancer in a patient in the Antarctica, cut off from access to medical facilities for 6 months a year, there are significant problems with telecytology. A smear contains thousands of images that should be reviewed before reaching a diagnostic verdict. Transmitting and receiving this large number of images is time consuming at both ends. Finding a suitable consultant who would be willing and able to spend hours reviewing microscopic images on a television screen would not be practical as a daily duty. Reservations about the use of preselected fields of view in diagnostic telecytology were also expressed by Mairinger and Geschwendter (1997).

On the other hand, **telecytology as a teaching tool** has already achieved much success and

will continue to be a desirable addition to any teaching system.

THE ROLE OF CLINICIANS IN SECURING CYTOLOGIC SAMPLES

The quality of the cytologic diagnosis depends in equal measure on the excellence of the clinical procedure used to secure the sample, the laboratory procedures used to process the sample, and the skills and experience of the interpreter. The **clinical procedures** used to secure cytologic samples from various body sites and organ systems are discussed in appropriate chapters. The success and failure of the method often calls for close collaboration between the clinician and the cytopathologist. **Experience and training cannot be described in these pages except for outlining of a few basic principles:**

- **Familiarity with diagnostic options** available for the specific organ or organ system;
- **Securing in advance all instruments and materials** needed for the procedure;
- **If necessary or in doubt, a discussion between and among colleagues** to determine the optimal procedure, which may be of benefit to the patient.

The choice of methods depends on the type of information needed. Cancer detection procedures, for example,

P.17

those used for detecting precursor lesions of carcinoma of the uterine cervix, have a different goal than diagnostic procedures required to establish the identity of a known lesion.

The issue of turf, that is, who is best qualified to perform the procedure, is often dictated by clinical circumstances. A skilled **endoscopist or interventional radiologist** cannot be replaced and must be thoroughly familiar with the optimal technique of securing diagnostic material. In many ways, the diagnostic cytologic sample is **similar to a biopsy** where the territories are well defined, that is, the clinician obtaining the sample for the pathologist to interpret. However, in diagnostic cytology, there are **gray areas**, such as the needle aspiration of palpable lesions (FNA), where special skills must be applied for the optimal benefit to the patient. In such situations, optimal training and experience should prevail (see Chap. 28).

In general, material for cytologic examination is obtained either as **direct smears**, prepared by the examining physician, gynecologist, surgeon, trained cytopathologist, or paramedical personnel from instruments used to secure the samples at the time of the clinical examination, or as **fluid specimens**, that are forwarded to the laboratory for further processing. Regardless of the method used, **it is essential for the clinician to provide accurate clinical and laboratory data** that are often extremely important in the interpretation of the material.

Of the two procedures, the preparation of smears is by far the more difficult.

Preparation of Smears

Smears can be prepared from material **obtained directly from target organs** by means of simple instruments (e.g., the uterine cervix) or **from brushes** used to sample hollow organs (e.g., the bronchi or organs of the gastrointestinal tract). For most diagnostic purposes, **well-prepared, well-fixed, and stained smears are easier to interpret than air-dried smears, which have different microscopic characteristics, unless the observer is trained in the interpretation of this type of material.** Still, many practitioners of **aspiration biopsies (FNAs)**, particularly those who follow the Swedish school, favor **air-dried smears fixed in methanol and stained with hematologic stains** (see Chap. 28). In this book, every effort has

been made to present the cytologic observations based on the two methods side-by-side.

It is important to place as much as possible of the material obtained on the slide and to prepare a **thin, uniform smear**. Thick smears with overlapping cell layers are difficult or impossible to interpret. Considerable skill and practice are required to prepare excellent smears by a single, swift motion without loss of material or air drying.

Preparation of **smears from small brushes used by endoscopists to investigate hollow organs may be particularly difficult**. A circular motion of the brush on the surface of the slide, while rotating the brush, may result in an adequate smear. Too much pressure on the brush may result in **crushing of material**. If the person obtaining diagnostic material is not familiar with the technical requirements of smear preparation, competent help must be secured in advance. If none is available, the brushes can be **put into liquid fixative and forwarded to the laboratory for smear preparation**.

Except in situations in which the preparation of air-dried material is desirable (see above and Chap. 28), **immediate fixation of material facilitates correct interpretations**. Two types of fixatives are commonly used: **fluid fixatives and spray fixatives**. Both are described in detail in appropriate chapters and summarized in Chapter 44.

In addition to the customary commonly available fixatives, such as 95% alcohol, new commercial fixatives have become available. One such fixative is CytoRich Red (TriPath Corp., Burlington, NC) that has found many uses in the preparation of various types of smears. This fixative preserves cells of diagnostic value while lysing erythrocytes (see Chaps. 13 and 44 for further discussion of this fixative). In general fixation of smears, 15 minutes is more than adequate to provide optimal results. **Errors of patient identification or occurrence of “floaters,” or free-floating cells, may cause serious diagnostic mishaps. If automated processing** of a cytologic sample is desired, the commercial companies provide vials with fixatives accommodating collection devices or cell samples. For further discussion of these options, see Chapters 8 and 44.

Spray fixatives provide another option. Their makeup and mode of use are described in detail in Chapter 44. When correctly used, spray fixatives protect the smears from drying by forming an invisible film on the surface of the slides. If spray fixatives are selected (and they usually are easier to handle than liquid fixatives), they should be applied **immediately** after the process of smear preparation has been completed. The use of spray fixative requires some manual dexterity, described in detail in the appendix to Chapter 8.

Collection of Fluid Specimens

Fluid specimens may be obtained from a variety of body sites, such as the respiratory tract, gastrointestinal tract, urinary tract, or effusions, and the clinical procedures used in their collection are described below. As is discussed in detail in Chapter 44, **unless the laboratory has the facilities for immediate processing of fluid specimens, it is advisable either to collect such specimens in bottles with fixative prepared in advance or to add the fixative shortly after collection**. The **common fixative of nearly universal applicability to fluids is 50% ethanol or a fixative containing 2% carbowax in 50% ethanol** (see Chap. 44). It is sometimes advisable to collect bloody fluids with the addition of **anticoagulants, such as heparin. Ether-containing fixatives should never be added to fluids**.

The volume of the fluid rarely need be larger than 100 ml. Screw cap bottles of 250-ml content, containing 50 ml of fixative, are suitable for most specimens. Generally, the volume of the

fixative should be the same or slightly in excess of the volume of the fluid to be studied. **The fluids**

P.18

may be processed either as smears or cell blocks. The methods of preparation are described in Chapter 44.

BASIC PRINCIPLES OF THE INTERPRETATION AND REPORTING OF CYTOLOGIC SAMPLES

Diagnostic cytology is the **art and science** of the interpretation of cells from the human body that either exfoliate (desquamate) freely from the epithelial surfaces or are removed from tissue sources by various procedures, summarized above. The **cytologic diagnosis**, which is often more difficult than histologic diagnosis, **must be based on a synthesis of the entire evidence available**, rather than on changes in individual cells. If the cytologic material is adequate and the evidence is complete, a definitive diagnosis should be given.

Clinical data are as indispensable in cytologic diagnosis as they are in histologic diagnosis. Definitive cytologic diagnosis must be supported by all the clinical evidence available. Of the greatest possible importance in maintaining satisfactory results in diagnostic cytology is the **uniformity of the technical methods employed in each laboratory**. The cytologic diagnoses are frequently based on minute alterations of cytoplasmic and nuclear structure. These alterations may not be very significant, per se, unless one can be sure that variations due to the technique employed can be safely eliminated. However, as in any laboratory procedure, **situations may arise in which the evidence is too scanty for an opinion, and this fact must be reported appropriately**. The imposition of rigid reporting systems, such as the **Bethesda system** for reporting cervicovaginal material, summarized in Chapter 11, and found to be of value in securing epidemiologic or research data, may sometimes deprive the pathologist of diagnostic flexibility. These issues are discussed at length in reference to all organs and organ systems.

Before attempting the cytologic diagnosis of pathologic states, it is very important to acquire a **thorough knowledge of normal cells** originating from a given source. "Normal" includes variations in morphology caused by physiologic changes that depend on the organ of origin. Moreover, the cells may show a variety of morphologic changes that, in the absence of cancer, may result in substantial cellular abnormalities. Among these, one should mention primarily **inflammatory processes of various types; proliferative, metaplastic, degenerative, and benign neoplastic processes**; and, finally, **iatrogenic alterations** that occasionally may create a truly malicious confederacy of cellular changes set on misleading the examiner.

The understanding of the basic principles of cell structure and function, although perhaps not absolutely essential in the interpretation of light microscopic images, nevertheless adds a major dimension to the understanding of morphologic cell changes in health and disease. Furthermore, basic sciences have already been of value in the diagnosis of human disease. For these reasons, in the initial chapters of this book, there is a reasonably concise summary of some of the basic knowledge of cells and tissues.

QUALITY CONTROL

Much has been said lately about **quality control** in cytology. On the assumption that this branch of human pathology is practiced with the skill and technical expertise similar to that observed elsewhere in medicine today, **the best quality control is generated by the follow-**

up of patients. Constant referral to tissue evidence and the clinical course of the disease and, if death intervenes, to the postmortem findings, are the only ways to secure one's knowledge. It is a pity that currently there is a pervasive tendency to regard a postmortem examination as a tedious and generally wasteful exercise. There is abundant evidence that, in spite of enormous technical progress, the **autopsy** still provides evidence of clinically unsuspected disease in a significant **percentage of patients. Diagnostic cytology must be conceived of and practiced as a branch of pathology and of medicine. Any other approach to this discipline is not beneficial to the patients.**

2

The Basic Structure of the Mammalian Cell

A cell is a self-contained fundamental unit of life. All cells are tridimensional, space-occupying structures, although when spread on a glass slide and viewed through the light microscope, they appear to be flat. Each mammalian cell has **three essential components: cell membrane, cytoplasm, and nucleus** (Fig. 2-1 and see Frontispiece and Fig. 3-1). The cell membrane encloses the transparent cytoplasm. Within the cytoplasm, enclosed in its own membrane or envelope, there is a smaller, approximately spherical dense structure—the nucleus. **The nucleus is the principal repository of deoxyribonucleic acid (DNA),** the molecule governing the genetic and functional aspects of cell activity (see Chap. 3). Although some mammalian cells, such as erythrocytes or squamous cells, may lose their nucleus in the final stages of their life cycle, even these final events are programmed by their DNA. **All nucleated cells are classified as eukaryotic cells (from Greek, *karion* = kernel, nucleus) in contrast with primitive cells, such as bacteria, wherein the DNA is present in the cytoplasm but is not enclosed by a membrane as a distinct nuclear structure (prokaryotic cells).** Many of the fundamental discoveries pertaining to the molecular biology of cells were made in prokaryotic cells, documenting that all basic biochemical manifestations of life have a common origin. Families of cells differ from each other by their structural features (morphology) and by their activities, all programmed by DNA. The recognition of these cell types and their alterations in health and disease is the principal task of diagnostic cytology. **All cells share the fundamental structural components** that will be described in these pages.

MICROSCOPIC TECHNIQUES USED IN EXAMINATION OF CELLS

Cells can be examined by a variety of techniques, ranging from the commonly used light and electron microscopy to newer techniques of confocal and digital microscopy. Additional information on cell structure, derivation, and function can be obtained by immunocytochemistry and by in situ hybridization of cell components. The techniques required for special procedures will be described in the appropriate chapters. This brief summary will serve as an introduction to the description of the fundamental structure of the cell.

Light Microscopy

Bright-Field Light Microscopy

Bright-field light microscopes are optical instruments that allow the examination of cells at magnifications varying from 1× to 2,000×, using an appropriate combination of lenses. The highest resolution of the commonly used light microscopes, that is, the ability of the instruments to visualize the smallest objects, is limited by the wavelength of the visible spectrum of light, which is about 0.5 μm. The principles of bright-field light microscopy have been described in numerous books and manuals and need not be repeated here. It is assumed that the readers

have a working knowledge of these instruments. Suffice it to say that the **quality of the optics used, skill in the adjustment of the illumination, and the depth of the microscope's focus are essential**

P.22

in evaluating the cellular preparations. In practice of clinical cytology, bright-field microscopy satisfies nearly all requirements for the diagnostic assessment of cells. The same technique is used in assessing the results of special stains and of immunocytochemistry.

Figure 2-1 Benign human fibroblasts from a female patient in tissue culture. *A.* Low-power view shows the relationship of the cells, which do not overlap each other. *B.* High-power view shows delicate cytoplasm, generally oval or round nuclei with small multiple nucleoli. Sex chromatin indicated by arrow (*A*: $\times 250$; *B*: $\times 1,000$) (Alcohol fixation, Papanicolaou stain. Culture by Dr. Fritz Herz, Montefiore Hospital. From Koss LG. Morphology of cancer cells. *In* Handbuch der allgemeinen Pathologie, vol. 6, Tumors, part I. Berlin, Springer, 1974, pp 1-139.)

Preparation of Cells for Bright-Field Light Microscopic Examination

The cells are usually prepared for a light microscopic examination in the form of **direct smears** on commercially available glass slides of predetermined thickness and optical quality. Samples of cells suspended in fluid may be placed on glass slides by means of a special centrifuge, known as a **cytocentrifuge**, or a similar apparatus. A cell suspension may also be **filtered across a porous membrane**. The cells deposited on the surface of such membranes may either be examined directly or may be placed on glass slides by a process of **reverse filtration**. Cell samples may also be studied in histologic-type sections, after embedding of the sediment in paraffin (a technique known as the **cell block**). For details of these techniques, see Chapter 44.

Fixation.

Fixation of cell preparations is a common procedure having for its purpose the best possible **preservation of cell components** after removal from the tissue of origin. A variety of fixatives

may serve this purpose, all described in Chapter 44. However, diagnostic techniques may also be based on **air-dried cell preparations, either unfixed or postfixes in methanol**, which introduce a number of useful artifacts. Such techniques are used in hematology and in aspiration biopsy samples.

Staining.

Optimal results in bright-field microscopy are obtained on stained preparations that provide visible contrast and discrimination among the cell components. A variety of stains, described in Chapter 44, can be used to best demonstrate various cell components. Common stain combinations use hematoxylin and its variants as the nuclear stain and eosin or its many variants as the cytoplasmic stain. Examples of stains of this type include the **hematoxylin-eosin stain** and the **Papanicolaou stain**, which allow for a good visualization of the principal components of the cell, by contrasting the nucleus and the cytoplasm. Other stains in common use include methylene blue, toluidine blue, and **Giemsa colorant** that provide less contrast among cell components but have the advantage of rapidity of use. An example of cells fixed in alcohol and stained by the Papanicolaou method is shown in Figure 2-4.

Phase-Contrast Microscopy

Phase-contrast microscopy utilizes **the difference in light diffraction** among the various cell components and special optics that allow the visualization of components of **unstained cells**. The **Nomarski technique** is a variant of phase contrast microscopy that is particularly useful in the **study of cell surfaces**. Either technique may be applied to the study of **living cells** in suspension or culture and, when coupled with time-lapse cinematography or a television system, may

P.23

provide a continuous record of cell movements and behavior. These techniques are particularly useful in experimental systems, as they may document the differences in cell behavior under various circumstances, for example, after treatment of cultured cells with a drug or during a genetic manipulation. The systems also allow the study of events, such as **movement of chromosomes during cell division**, or mitosis. An example of the application of the Nomarski technique to a cell culture is shown in Figure 2-2 .

Fluorescent Microscopy

Cells or cell components stained with fluorescent compounds or **probes** can be visualized with the help of microscopes provided with special lenses and a **source of fluorescent light**, such as a mercury bulb or a laser, tuned to an appropriate wavelength, exciting fluorescence of the probe. In highly specialized commercial systems, the amount of fluorescence can be measured in individual cells or families of cells, and may serve to quantify various cell components. A somewhat similar system is used in **flow cytometry** (see Chap. 47). Fluorescence microscopy is particularly valuable in the procedures known as **in situ hybridization**, with the purpose of documenting the presence of chromosomes, chromosomal aberrations, or individual genes (see Fig. 2-31 and Figs. 4-26, 4-27, and 4-29). Fluorescent microscopy is also useful in identifying certain **components of cell cytoplasm or cell membranes**, using specific antibodies. Application of fluorescent microscopy and other techniques to the study of **living cells** was summarized in a series of articles on biologic imaging in the journal, *Science*, 2003.

Figure 2-2 Time-lapse cinematography, using Nomarski interference contrast optics, shows events in the merging of two colonies of cultured human cancer cells, line C41. (In this technique the cell nuclei are seen in the form of craters wherein are located the nucleoli shown as small elevations.) *A.* Beginning of sequence: two adjacent colonies. *B.* Sixteen minutes later: a cytoplasmic bridge between the two colonies has been established. *C.* Twenty-six minutes later: the area of merger has increased in size. *D.* Ninety-five minutes later: the merger has progressed to the point at which several cells in both colonies are fused. (Courtesy of Dr. Robert Wolley, Montefiore Hospital.)

Confocal Microscopy

Using a system of complex optics and a laser, the technique, combined with phase and fluorescent microscopy in complex and costly instruments, allows the **visualization of cells and tissues in slices**, separated from each other by approximately 1 μm . The images of the slices can be combined on a computer to give a three-dimensional picture of the cell or tissue and their components. This technique is applicable to individual cells or cell clusters that can be examined layer-by-layer.

P.24

Digital Microscopy

With the wide availability of sophisticated computers, it has become possible to **transform cell images into digits, that is, numerical values**. The images are recorded by television or digital cameras, transformed into numerical values and stored in the computers' memory, on videotape, or on a videodisc. The original images can be reconstituted when needed. Such images, often of outstanding quality, can be manipulated with the help of special software. Images from several different sources can be assembled into plates suitable for publications or special displays. The colors of the displays can be adjusted for optimal quality of images. Many

new plates in this book have been prepared with this technique. Digital microscopy can also be applied to electron microscopic images (Shotton, 1995).

Digital microscopy has been extensively applied in **analytical and quantitative studies of cells and cell components**. These techniques allow discrimination among families of cells of similar appearance but different biologic or clinical significance. They can also be applied to a variety of **measurements of cell components, such as DNA**, as discussed in Chapter 46. Variants of these techniques have been used in commercial instruments for automated or semiautomated analysis of cell populations.

Digital microscopy is suitable for direct transmission of images via cable or satellites to remote locations (**telepathology or telecytology**) for **teaching or diagnostic purposes**, as discussed in Chapters 1 and 46. Demonstration projects of this technology have documented that such images are of good quality when examined at the receiving stations. The images can be studied under variable magnification factors, thus allowing for diagnostic opinions. Transmissions of images by Internet have been extensively used for teaching. It is conceivable that, in the future, central telepathology consultation centers will be established to advise pathologists on difficult cases. At present, the systems are limited by cost, the speed of transmission, and by the availability of knowledgeable consultants to perform such services.

Electron Microscopy

Transmission Electron Microscopy

Transmission electron microscopic technique utilizes certain **optical properties of a fixed beam of electrons** to illuminate the object. The images are captured on photographic plates. Extremely thin sections of tissues or cells (50 to 100 nm) and staining with heavy metals are required. Special fixation and embedding techniques must be used. The method allows a unique insight into the fine structure of the cell. Most of the images in this chapter were obtained by this technique.

Scanning Electron Microscopy

In the commonly used mode, the scanning electron microscopy technique utilizes a **rapidly moving beam of electrons to scan the surface of cells** or other objects. The cells are dehydrated, fixed, and coated with a thin metallic layer, usually of gold and palladium. The metal forms an exact replica of the cell surface. The beam of electrons glides over the metallic surface, and the reflected electrons form an image that may be registered on a photographic plate (Fig. 2-3) or on a fluorescent screen. Scanning electron microscopy is also applicable to the **freeze-fracture technique**, described below.

Figure 2-3 Scanning electron microscope view of cells in pleural effusion. The small doughnut-like cells are erythrocytes, the large chestnut-like cells are cancer cells. Intermediate-sized cells are macrophages, mesothelial cells, and leukocytes. The surfaces of the large cancer cells are covered by microvilli. ($\times 300$.) (Courtesy of Dr. W. Domagala, Montefiore Hospital.)

Other Techniques

Several other special techniques, such as **interference microscopy** and **x-ray diffraction microscopy**, have been used for a variety of investigative purposes. **Scanning-tunneling microscopy** is a new tool for visualization of surfaces of molecules such as DNA. This technique has no applications to diagnostic cytology.

Magnetic resonance, a technique widely used in imaging of the human body (**MRI**), is applicable to the study of tissues in vitro and to histologic sections as **magnetic resonance microscopy** (Huesgen et al, 1993; Sbarbati and Osculati, 1996; Johnson et al, 1997). The technique is based on magnetic gradients that produce a shift in hydrogen ions' alignment in water content of the living tissues, creating images that can be captured by computer and recorded on a photographic plate. Because of its low resolution, the practical value of this technique remains to be determined.

THE COMPONENTS OF THE CELL

The components of the cell will be described under three main headings: **the cell membrane**, **the cytoplasm**, and **the nucleus** (see Frontispiece). Whenever possible, the description will comprise light and electron microscopic

observations. The purely morphologic description has limited bearing on the intimate biochemical interrelationship of the cell components. The reader is referred to Chapter 3 and the appended references for further information.

The Cell Membrane

The cell membrane is the outer boundary of the cell, **facilitating and limiting the exchange of substances between the cell and its environment**. In light microscopy, the membrane of well-fixed mammalian cells cannot be seen. The cell's periphery appears as a thin condensation (Fig. 2-4).

In transmission electron microscopy, the cell membrane appears as a well-defined line measuring approximately 75 Å in width (Fig. 2-5). **The membrane is composed of three layers**, each about 25 Å thick (see Frontispiece and Fig. 2-18). The inner and the outer dense (electronopaque) layers are separated by a somewhat wider lucent central layer. Similarly constructed membrane systems are observed in a variety of intracytoplasmic components within the cell, such as the mitochondria and the endoplasmic reticulum (see below). The term **unit membrane** is often used in reference to cell membranes in general.

Davson and Danielli (1952) proposed that the plasma membrane is composed of a double lipid layer coated by polypeptide chains of protein molecules. This concept was acceptable so long as it readily explained certain physicochemical characteristics (semipermeability) of cell membranes. However, it has become evident that the cell membrane, far from being a passive envelope of cell contents, plays a critical role in virtually every aspect of cell function. Thus, **the cell membrane regulates the internal environment of the cell, participates actively in recognition of the external environment and in transport of substances to and from the cell, determines the immunologic makeup of the cells, and accounts for the interrelationship of cells**.

Figure 2-4 Human bronchial cells, oil immersion. *A.* The focus was on the region of the cell membrane (M) and the nucleus. Within the latter there is a single nucleolus (NL) and several chromocenters. A sex chromatin body (S) adherent to the nuclear membrane may be observed. In this photograph the cilia appear to be anchored in a thick portion of the cytoplasm or a terminal plate. *B.* The focus was on cilia and their points of attachment within the cell. These are dense granules or basal corpuscles. The basal corpuscles form the so-called terminal plate.

The initial insight into the makeup and function of the cell membrane was based on the study of erythrocytes. Their membrane is made up of a **double layer (bilayer) of lipids**, formed by molecules provided with chains of fatty acids. The lipid molecules have one water-soluble (or hydrophilic) end and a water-insoluble (or hydrophobic) end. In the cell membrane, the electrically charged hydrophilic ends of the lipid molecules form the inner and the outer surfaces of the cell membrane, whereas the uncharged, hydrophobic chains of fatty acids are directed toward the center of the cell membrane, away from the two surfaces. Cholesterol molecules add structural rigidity to the cell membrane. Protein molecules of various sizes, functions, and configurations are located within the lipid bilayer (**integral proteins**) but also extend beyond the cell membrane, either to the outside or to the inside of the cell or both. Such **transmembrane proteins** provide communication between the cell environment and cell interior. The number, makeup, position, and mobility of the protein molecules account for specific, individual properties of cells and tissues by forming specific receptor molecules. Cell membranes are further characterized by molecules of carbohydrates that attach either to the lipids (glycolipids) or to the proteins (glycoproteins) and which are the repository of the

immunologic characteristics of the cell.

On the inner (cytoplasmic) aspect of the cell membrane, other protein molecules have been identified (**peripheral proteins**). Their function appears to be structural in **maintaining the integrity of the cell membrane and in providing communication between the cell membrane and the interior of the cell** (Fig. 2-6).

This complex asymmetric structure of the cell membrane cannot be demonstrated by conventional electron microscopy.

P.26

Therefore, to study the problem, special techniques have been applied, such as freeze-fracture. The **freeze-fracture technique** consists of three steps: very rapid freezing of cells and tissues, fracturing the tissue with an instrument, and preparation of a metal replica of the fractured surface that can be examined in the scanning electron microscope. It has been determined that the fracture lines are not distributed in a haphazard fashion but, rather, run along certain predetermined planes.

Figure 2-5 Electron micrograph of a segment of an arteriole. L = lumen, E = endothelial cells, M = smooth muscle cell, N = nucleus. Caveolae (CAV) and microvilli (MV) are evident in the endothelial cell. C = cell membrane; CF = collagen fibers with characteristic periodicity. Basement laminae (membranes) (BL) separate the endothelial cells from the muscle cells and the muscle cells from the connective tissue. ($\times 16,000$.)

Freeze-fracture of cell membranes disclosed **two surfaces** that, by agreement, have been named the **P face** and **E face** (Fig. 2-7). The P face represents the inner aspect of the cell membrane and contains numerous protruding protein particles. The E face represents the outer part of the cell membrane, which is relatively smooth, except for pits corresponding to the protein particles attached to the P face. A few protein particles usually remain attached to the E face. The density and distribution of the protein particles varies from cell type to cell type and may be substantially modified by immunologic and chemical methods, indicating that the

position of these particles within the cell membrane is not fixed. Thus, **the cell membrane is now thought to be a fluid-mosaic membrane**, as first proposed by Singer and Nicholson (1972). It may be conceived as a viscous structure that can adapt itself to changing needs and conditions by being permissive to movements of large molecules, such as protein particles. Fixation of cells solidifies the membrane. The freeze-fracture images represent only snapshots of the position of the protein particles at the time of fixation.

The freeze-fracture technique may also be used to study the structure of cell junctions (see Fig. 2-16) and the interior of other cell membranes, such as the nuclear envelope (see Fig. 2-27).

The **basic structure of intracellular membranes**, such as those composing the endoplasmic reticulum or mitochondria, appears to be **essentially similar to that of the cell membrane**, but differs in lipid/protein ratios and associated proteins and enzymes, reflecting the diversity of functions.

Cytoplasmic Interactions

Extensive work has been performed in recent years to establish links between the cell membrane and the cytoplasm. It is quite evident that this must be a very intimate association, as cell function depends on signals and nutrients received through the cell membrane. Also, the export of substances manufactured by the cell (or products of cell metabolism) must be regulated by interaction between the cytoplasm and the cell membrane.

Molecular biologic investigations of recent years have identified numerous protein molecules that contribute to the function of the cell membrane as a flexible link between the environment and the interior of the cell. Each one of these molecules interacts with other molecules and these interactions are growing increasingly complex. So far, only

P.27

small fragments of this knowledge have emerged. At the time of this writing (2004), no clear, cohesive picture has been formulated to explain how the cell membrane functions. Suffice it to say that there is good evidence that the cell membrane plays an important role in virtually every aspect of cell function in health and disease. Luna and Hitt (1992) discussed the **interaction between the cell skeleton and cell membrane as one example** of these interactions. Among the components of the cell skeleton that interact with the cell membrane are the intermediate filaments and tubules, described further on in this chapter.

Figure 2-6 Schematic representation of the current concepts of cell membrane.

The membrane is made up of two layers of lipids (*pins*), with points directed toward the center (uncharged hydrophobic ends) and pinheads (electrically charged hydrophilic ends) toward the two surfaces. The *black pinheads* indicate molecules of cholesterol, which add rigidity to the cell membrane. Integral protein molecules, represented by geometric figures of various shapes, are located within the bilipid layer, but also protrude from both surfaces. Symbolic representation of an emitting and receiving (dish) antennae show the cell's communications with its environment. On the inner aspect of the cell membrane, peripheral proteins (spectrin, actin) have been identified. These probably lend structural support to the membrane and provide communication between the cell membrane and the cytoplasm.

The cell membrane is also the site of molecules that define the immunologic features of the cell. For example, the **clusters of differentiation (CD)** and **blood group antigens** discussed elsewhere in this book, are located on the cell membranes.

Figure 2-7 Principle of freeze-fracture. The sharp wedge (*arrow*) separates the frozen membrane into two faces (P and E; see text) without disturbing the position of intermembrane protein particles or structures (see Figs. 2-16 and 2-27).

Coated Pits, Vesicles, and Caveolae: Mechanisms of Import and Export

Import, export, and transport of a variety of molecules within the cytoplasm takes place through pits and vesicles formed by invagination of cellular membranes. The largest of such vesicles observed on cell surfaces are known as **pinocytotic vesicles**. The pits and vesicles are coated by molecules of a complex protein, **clathrin**, which appears to be present in all cells. Clathrin is composed of three heavy and three light protein chains that form the scaffolds of the coats. Clathrin requires the cooperation of other proteins known as *adaptors* to fulfill its many functions, which include **capturing, sorting, and transporting molecules**. The molecular mechanisms of endocytosis have been extensively studied (Gillooly and Stemark, 2001). It may be assumed that each pit or vesicle is provided with specific receptors to a molecule or molecules of importance to the cell, and that it will recognize and selectively capture this molecule or molecules from thousands of molecules circulating within the fluid bathing the cell. Once the selected substance is captured, the vesicle closes and sinks into the cytoplasm to deliver its cargo to its appropriate destination. However, nature is extremely economical, and there is excellent evidence that the fragment of cell membrane that is used to form a vesicle is recirculated and returned to the surface in a different location to serve again. A similar mechanism is observed in removal or **phagocytosis** of hostile substances (or organisms, such as bacteria) that are recognized by the receptors on the cell surface. Removal of accumulated extracellular debris is another phagocytic function usually performed by specialized cells (**macrophages**) in a similar manner (see Fig. 5-13). A number of genetic disorders are now thought to be associated with **defective mechanisms of intracellular membrane transport** (Olkonen and Ikonen, 2000).

A reverse mechanism occurs in **export of molecules**, which are packaged into vesicles formed within the cell (mainly in the Golgi apparatus) (see below) and travel to the surface. The vesicles attach to the inner aspect of the cell membrane by means of specific receptors. After the merger, the cell membrane splits open, and the content of the vesicles is discharged into the circulating fluid bathing the cell.

Besides clathrin-coated pits, the cell membrane also forms specific small invaginations (50 to 100 nm in diameter) that are known as **caveolae**. In cross-section, the caveolae appear as

small, spherical vesicles in the adjacent cytoplasm (see Fig. 2-5). They are particularly prevalent in endothelial cells, smooth muscle cells, and type I pneumocytes (Schlegel et al, 1998; Couvet et al, 1997). The caveolae are composed of **caveolins**, a family of integrated membrane proteins, which interact with a number of signaling molecules and thus regulate the cell's responses to its environment (Okamoto et al, 1998). Thus, caveolins have been **implicated in cells' response to injury** and may play a role in human breast cancer (Engelman, 1998).

P.28

Specialized Structures of Cell Surfaces

Transmission electron microscopy has been helpful in elucidating some of the structural details of specialized structures of cell surfaces and the manner in which cells are attached to each other.

The Glycocalix

Specialized techniques of electron microscopy serve to demonstrate an ill-defined, **fuzzy layer of material on the free surfaces of cells**. This layer is referred to as **glycocalix** and appears to be composed primarily of glycoproteins containing residues of sialic acid. Although the thickness and, presumably, chemical makeup of glycocalix vary from one type of cell to another, its occurrence is a rather generalized phenomenon, the exact function of which is not well understood.

Cilia and Flagella: Motile Cell Processes

The cilia and flagella may be readily identified by light microscopy. Both are mobile extensions of the cell membrane and are capable of rapid movements. A **flagellum** is usually a single, elongated mobile part of the cell, as observed in spermatozoa. **Cilia** are shorter and multiple, usually functioning (batting) in a synchronous manner, for example, in cells lining the bronchial epithelium (see Fig. 2-4), or other epithelia, such as that of the fallopian tube and the endocervix. Cells bearing cilia are usually **polarized**; that is, they have a **specific spatial orientation** in keeping with their function: the cilia are usually oriented toward the lumen of an organ or tissue. The cilia are anchored in a thick, flat portion of the cell cytoplasm immediately adjacent to the surface, referred to as a **terminal plate** (see Fig. 2-4A). Careful observation reveals that the terminal plate is composed of a series of dense granules, or basal corpuscles, each belonging to a single cilium (see Figs. 2-4B and 2-8). **Cilia are rare in cancer cells.**

Figure 2-8 Diagrammatic representation of the structure of the ciliary apparatus (A) of a mollusk (*Elliptio*), (B) an amphibian (*Rana*), and (C) a mammal (mouse). Note the differences in attachment to the cytoplasm. (Fawcett DW. *Laryngoscope* 64:557-567, 1954.)

There is a remarkable **uniformity of ultrastructure of the motile cell processes** throughout the animal and the plant kingdoms. Each cilium or flagellum contains **11 microtubules**, of which **two are single and located within the center, and nine are double (doublets) and located at the periphery** (Figs. 2-9 and 2-10). The structure of the cilia and flagella is very similar to that of the centrioles (see below). Species differences do exist in the manner in which the cilia and the flagella are anchored within the cytoplasm (see Fig. 2-8).

Within recent years, considerable insight has been gained into the function of the cilia and flagella. These cell processes are composed of an intricate system of protein fibrils that glide against each other in executing the movements, which require a substantial input of energy, provided by mitochondria. For details of the current concepts of movements, see Satir (1965) and Sale and Satir (1977).

Microvilli and Brush Border

Microvilli are **short, slender, regular projections on free surfaces of cells** that can be visualized in electron microscopy

or light microscopy. The term **brush border** or **striated border** is applied to specialized cell surfaces provided with microvilli. The brush border is observed on the free surface of the intestinal mucosa (Fig. 2-11A and see Fig. 2-15). The regular, finger-like intestinal microvilli, delimited by the plasma membrane, measure approximately 1 μm in length and serve the function of increasing the useful surface of the cell. A similarly organized brush border is observed in the proximal segment of the renal tubules. Microvilli may be observed by light microscopy on the surface of various **normal human cells**, as **short, delicate, hair-like striations, best observed in air-dried and stained cells, spread on glass slides**. Scanning electron microscopy shows microvilli, as finger-like, slender structures, projecting from the surface of the cell. **Long and irregular microvilli that occur on the surfaces of cancer cells are much easier to see in light microscopy and are occasionally of diagnostic help.** These observations are discussed in detail in Chapter 7 and are illustrated in Figures 7-7, 7-8, 7-9, 7-10, 7-11, 7-12, 7-13 and 7-14.

Figure 2-9 Diagrammatic representation of a cilium (A) and of the principal piece of mammalian sperm flagellum (B). Note the similarity of the basic structure, with two single microtubules in the center and nine double microtubules at the periphery. This structure of cilia is encountered throughout the plant and the animal kingdoms. (Fawcett DW. *Laryngoscope* 64:557-567, 1954.)

Figure 2-10 Electron micrograph of cross- and longitudinal sections of cilia from human endocervical cells. The nine peripheral double microtubules and the two central single microtubules are well shown. ($\times 80,000$.) (Courtesy of Dr. H. Dembitzer, Montefiore Hospital.)

Cell Contacts

The relationship of cells to one another within the same tissue or within adjoining tissues is of paramount importance for the structural integrity and function of all organs (see Fig. 2-11). These relationships are regulated by cell membranes, which form a variety of cell contacts and cell attachments. It is not known as yet whether the cell attachments are formed on predetermined specialized areas of cell surfaces, or incidental to haphazard cell contacts.

From the morphologic point of view, a number of structural cell contacts have been identified. These are the **desmosomes**, the **junctional complexes**, and the **gap junctions** (Fig. 2-12).

The Desmosomes and Hemidesmosomes

The structure of cell attachments, especially within the epithelia, has been of interest to biologists and pathologists alike for over a century. Early on, it has been noted in light microscopy that, within the squamous stratified epithelia, the cells are attached to each other by means of cytoplasmic extensions, named **intercellular bridges**. In phase microscopy, fine fibrils, named *tonofibrils*, may be seen converging on the areas connecting the unfixed, unstained cells. For many years, it has been known that, in the centers of the intercellular bridges, there existed small dense structures, variously referred to as *granules* (Ravie) or *nodes* (Bizzozero) and currently referred to as **desmosomes**. Electron microscopic studies have demonstrated that the desmosomes represent **points of adhesion of two adjacent cells** (see Figs. 2-11, 2-12 and 2-13). The cytoplasm of adjacent cells remains firmly attached at the points of desmosomal adherence but, owing to artifacts of

fixation, it shrinks elsewhere. The elongated desmosomebound portions of the cytoplasm constitute the intercellular bridges seen in light microscopy. Recent studies show that molecules of C-cadherin are an essential component of desmosomes (He et al, 2003).

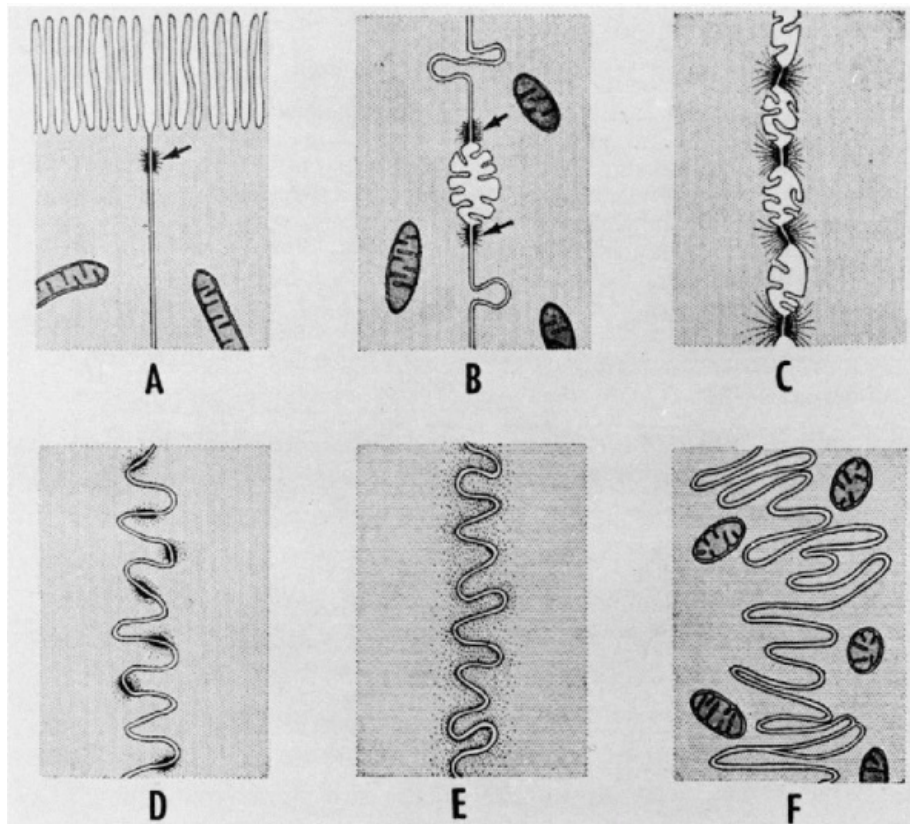

Figure 2-11 Diagrammatic representation of several types of specialization found on the surfaces of contact between adjacent cells. *A.* On the interface between columnar epithelial cells of the intestine, desmosomes (*arrow*) are frequently seen near the free surface showing striated border. *B.* On the contact surfaces of liver cells, desmosomes occur (*arrows*) on either side of the bile capillary. Near these are stud-like processes that project into concavities on the surface of the adjacent cell. *C.* In the stratified squamous epithelium of the rodent vagina, the cell surfaces are adherent at the desmosomes and retracted between, giving rise to the so-called intercellular bridges of light microscopy. A continuous system of intercellular spaces exists between bridges. Projecting into these spaces are a few short microvilli. *D.* In the stratum spinosum of the tongue, adjoining cells have closely fitting corrugated surfaces. Numerous desmosomes are distributed over the irregular surface. *E.* The partially cornified cells of the superficial layers of stratified squamous epithelium apparently lack desmosomes, but the ridges and grooves of the cell surfaces persist. *F.* An extraordinarily elaborate intercrecence of cell surfaces is found in the distal convoluted segment of the frog nephron. (Fawcett DW. Structural specializations of the cell surface. *In* Palsy SL (ed). *Frontiers in Cytology*. New Haven, Yale University Press, 1958.)

The **fine structure of a desmosome**, or *macule adherens* (from Latin = adhesive area; plural, *maculae adherentes*), is fairly uniform in most tissues examined to date: within each cell, at the region of localized contact of two cells, there is a dense plaque adjacent to the cell membrane,

made up of converging cytoplasmic actin microfilaments (tonofibrils). The two cell membranes do not appear modified. Within the intercellular substance, there is a dense central lamina. Very slender filaments run between the central lamina and the adjacent cell membranes (see Fig. 2-13).

Figure 2-12 Diagrammatic representation of the three principal types of cell junctions. The tight junction (TJ) is formed by fusion of the two outer layers of adjacent cells. It is impermeable to most molecules. The gap junction (GJ) serves the purposes of cell-to-cell communication. The desmosomes (D) are button-like, extremely tough cell junctions that are particularly well developed in protective epithelia, such as the squamous epithelium.

The desmosomal apparatus is operational in all epithelia and many other tissues, but the details of the structure may vary from one tissue type to another. For instance, the squamous epithelium of the genital tract may be structurally somewhat different from the squamous epithelium of other

P.31

organs. Burgos and Wislocki (1956) demonstrated the existence of intercellular canaliculi in the rodent vagina during estrus. Such canaliculi conceivably serve as channels for metabolites, etc. and, perhaps, are instrumental in bringing about the marked cyclic changes in the vaginal epithelium in these animals (see Fig. 2-11).

Figure 2-13 Desmosomes and actinfilaments (tonofibrils). Epidermis of human vulva. Electron micrograph of a portion of two adjoining epithelial cells showing actin filaments attached to two desmosomes (D). The filaments do not transverse cell boundaries. Note within the intercellular space a central dense lamina (*arrow*), a part of the desmosome structure. Bundles of filaments (T) may be observed within the cytoplasm. ($\times 54,400$.)

Recent investigations of cytoskeleton (see below) disclosed that desmosomes are biochemically complex structures containing many different **filamentous proteins**, some of which are **desmosome specific**. Among the latter, specific adhesion proteins (**adherins**) have been identified in cytoplasmic plaques. Other protein components of desmosomes are **desmoplakins** and **desmogleins**. The desmosomes also contain intermediate filaments of various molecular weights. It has been documented that the makeup of desmosomes varies in different cell and tissue types (Franke et al, 1982, 1994). With the development of specific monoclonal antibodies to these proteins, the presence of desmosomal proteins may now be used as a means of tissue identification and diagnosis of diseases (Franke et al, 1989, 1994; Schmidt et al, 1994).

Hemidesmosomes (half-desmosomes) are observed at the attachment points of epithelial basal cells to the basement lamina. The half-desmosome is morphologically somewhat similar to the desmosome: there is a thickening of a limited area of the cytoplasm of a basal cell adjacent to the cell membrane, upon which converge cytoplasmic fibrils. However, the apposed basement membrane shows merely a slight thickening, which contains slender filaments. An intermediate thickening, or membrane, is usually present within the fibrils of the hemidesmosome (Fig. 2-14). Jones et al (1994) documented that the hemidesmosomes serve as **connectors between the extracellular matrix and the intermediate filaments in the cytoplasm of the cell**. The mechanisms of cell adhesion molecules to the extracellular matrix were reviewed by Hutter et al (2000).

The Junctional Complexes

Farquhar and Palade (1963) described a particular type of attachment of epithelial cells, known as the junctional complex, located along the lateral surfaces of the cells adjacent to the lumen (Fig. 2-15). The junctional complex is composed of **three parts**. The **tight junction** (*zonula occludens*), closest to the lumen, represents an area of fusion of the outer leaflets of the plasma membranes of two adjacent cells. The molecular mechanisms of formation of this junction were discussed by Knox and Brown (2002). This cell junction contains the adhesion molecule, E-cadherin (Franke et al, 1994). The **intermediate junction** (*zonula adherens*) is characterized by the presence of an intercellular space, separating areas of cytoplasmic density occurring in each of the participating cells. The third part of the junctional complex is a **desmosome** (*macula adherens*). On the surface of certain epithelia, for example, in the small intestine, the tight junctions form an occlusive network that is essentially not permeable to molecules, even of a very small size, and presumably, synchronizes the function of these epithelia. Thus, nutrients cannot penetrate the seal between the cells, but are absorbed by the cell surfaces facing the lumen. A similar arrangement is encountered on the surfaces of many other epithelia in contact with a fluid medium, such as the renal tubules, bile canaliculi, and ependymal cells. Freeze-fracture of tight junctions shows a continuous network of ridges and grooves at the site of membrane fusion (Fig. 2-16A).

P.32

Figure 2-14 Half-desmosomes. Electron micrograph of the basal portion of the epithelial cell (E) of rat bladder and the basement lamina (BL). The half-desmosomes (D) are fan-shaped areas of increased density owing to numerous converging fine fibrils. An intermediate membrane (IM) is present between the cell membrane (CM) and the basement lamina. Dense material, possibly fibrillar, located between the cell membrane and the basement lamina completes the half-desmosome. (× 54,600.)

The Gap Junctions (Nexus Junctions)

First observed in the cardiac muscle and, subsequently in a variety of other tissues, the gap or nexus junctions were identified as **specialized areas of cell contact**. In transmission electron microscopy, gap junctions appear as well-demarcated areas of merger between two adjacent cells, somewhat less than 200 Å in thickness. The junction is composed of seven layers, three of which are electrontranslucent and are sandwiched in between electron-dense layers (see Fig. 2-12). The central electron-lucent zone (or gap) is composed of small hexagonal subunits, forming the **channels of communication between adjacent cells** (Revel and Karnovsky, 1967). Freeze cleaving confirmed that the gap junction is a highly specialized area of cell contact, displaying membrane-associated particles in a hexagonal array (see Fig. 2-16B). There are at least two different types of gap junctions, with a somewhat different arrangement of particles.

The gap junction channels are composed of a diverse family of proteins, named **connexins** (Donaldson et al, 1997). **The gap junctions have multiple functions: they provide cell-to-cell communications of essential metabolites and ions and may serve as electrical synapses** (Leitch, 1992). It has been shown that defects in connexins may be associated with human diseases (Paul, 1995; Spray, 1996). Thus, the gap junctions and the associated proteins are essential to function and integrity of tissues.

The Cytoplasm and Organelles

The cytoplasm is the component of the cell, located between the nucleus and the cell membrane. Depending on the type and origin of the cell, the cytoplasm may present a variegated light microscopic appearance. Its **shape, size, and staining properties vary greatly** and will be described in detail for the various tissues and organs. In living cells, there is an intense movement of particles within the cytoplasm.

In conventional **light microscopy**, various products of cell metabolism may be seen in the cytoplasm, often appearing as **granules** or **vacuoles**. The latter are round or oval structures, generally with an unstained or a faintly stained center. Their contents may be identified by special techniques.

Electron microscopic investigation of cells, coupled with sophisticated biochemical methods, has shed considerable light on the basic structure of the cytoplasm and of the major organized cytoplasmic components or organelles.

Figure 2-15 Junctional complex. Electron micrograph of intestinal-type epithelium observed in a rare nasal tumor of man. The component of the junctional complex may be observed: tight junction (TJ), intermediate junction (IJ), and the desmosome (D). Other desmosomes (D', D'') may be observed below. Note also the microvilli (MV), seen in longitudinal and cross section, and mitochondria (M), some with intramitochondrial dense granules. Also note dense bodies (DB), which may represent secretory granules ($\times 22,800$.) (Courtesy of Dr. Robert Erlandson, Sloan-Kettering Institute for Cancer Research, New York.)

Ultrastructure of the Cytoplasm

The cytoplasm is composed of **organized cell components, or organelles**, the **cytoskeleton**, and a **cytoplasmic matrix**. The organized components of the cytoplasm comprise the membranous systems, ribosomes, mitochondria, lysosomes, centrioles, microbodies, and miscellaneous structures.

The Membranous System

The membranous system **is composed of the endoplasmic reticulum and the Golgi complex.**

The Endoplasmic Reticulum

The endoplasmic reticulum is a closed **system of unit membranes** forming tubular canals and flattened sacs or cisternae that subdivide the cytoplasm into a series of compartments. The membranes of the endoplasmic reticulum may be “**rough,**” that is, covered with **numerous attached granules composed of ribonucleic acid (RNA) and proteins (RNP granules or ribosomes;** see below), or “**smooth,**” **free of any particles.** The amount and structural forms of endoplasmic reticulum vary from one cell type to another. In general, **rough endoplasmic reticulum** is abundant in cells with **marked synthesis of proteins** for export—for instance, in the pancreas or the salivary glands, see Figure 2-17. In light microscopy, the RNA-rich cytoplasmic areas (once named *ergastoplasm*) **stain bluish with hematoxylin.** This feature is commonly observed in metabolically active cells. **Smooth cytoplasmic reticulum is abundant in cells that synthesize various steroid hormones.**

P.34

Figure 2-16 Electron micrographs of freeze-fracture preparations showing a tight junction (A) and a gap junction (B). A. The tight junction (zonula occludens) appears in freeze-fracture images as a continuous meshwork of ridges and grooves representing the sites of membrane fusion (*arrows*). Epidermis of the transparent catfish (*Kryptoterus*). B. The appearance of gap junctions is quite different from the tight junction in that they are made up of plaques (GJ) of closely packaged particles. The particles measure about 9 nm in diameter and are believed to be the sites at which hydrophilic channels bring about electrical coupling between cells. Myocardium of a tunicate (*Ciona*). (Unpublished data of RB Hanna and GD Pappas, Albert Einstein College of Medicine, New York. Courtesy of Dr. Pappas.)

Note the ribosomes (RNP particles) attached to the membranes of the endoplasmic reticulum. Free ribosomes are also present in the space between the membranes. ($\times 43,000$.) (Courtesy of Dr. Bernard Tandler, Sloan-Kettering Institute for Cancer Research, New York.)

The Golgi Complex

First described by Golgi in 1898, this organelle consists of a **series of parallel, doughnut-shaped flat spaces or cisternae and spherical or egg-shaped vesicles demarcated by smooth membranes** (Fig. 2-18). In epithelial cells with secretory function, the Golgi complex is usually located between the nucleus and the luminal surface of the cells. Present evidence suggests that the Golgi complex **synthesizes and packages** cell products for the cells' own use and for export (Fig. 2-19). For example, the Golgi complex synthesizes structural proteins, such as the components of the asymmetric unit membrane observed in the urothelium (Hicks, 1966; Koss, 1969; see Chapter 22). The synthesis of the protein products occurs within the

cisternae of the Golgi complex. The **products for export** are packaged in the form of **vesicles lined by a single smooth membrane** derived from pinched off ends of the cisternae and is released into the cytoplasm (Fig. 2-20). A review of the mechanisms of protein sorting by the Golgi apparatus was provided by Allan and Balch (1999).

The Ribosomes

The ribosomes are submicroscopic particles measuring between 150 and 300 Å in diameter, depending on the technique used, and are composed of **RNA and proteins** in approximately equal proportions. They are ubiquitous and have been identified in practically all cells of animal and plant origin. In the cytoplasm, the ribosomes may be either floating free or they may be attached to the outer surface of the endoplasmic reticulum (see Fig. 2-17). It appears likely that the two types of ribosomes exercise different functions: the **free ribosomes** are primarily engaged in the production of proteins for the cell's own use, whereas **attached ribosomes** are responsible for protein production for export. A marked concentration of ribosomes (and hence proteins) confers upon the cytoplasm a basophilic staining (see above).

Each ribosome is composed of two, approximately round subunits of unequal size and has been compared to a **Russian doll**. Ribosomes may be joined together by strands of messenger RNA (mRNA) to form **aggregates or polyribosomes** that thus resemble a string of beads. The string may be either

P.36

open or closed. Ribosomes are attached to the membranes of the endoplasmic reticulum by the larger subunit.

Figure 2-18 Inactive Golgi complex. Electron micrograph of human labial salivary gland. In this type of cell, the Golgi complex (GC) is composed mainly of a series of parallel membranes made up of smooth reticulum (SR). Note the absence of ribosomes (see Fig. 2-17). C = cell (plasma) membrane; its three-layer structure, with a translucent middle layer is well seen in this photograph. ($\times 17,300$.) (Courtesy of Dr. Bernard Tandler, Sloan-Kettering Institute for Cancer Research, New York.)

The **ribosomal RNA (rRNA)** is manufactured in the nucleolus and transferred into the cytoplasm where it becomes associated with the protein component. At the conclusion of the process of protein synthesis, the ribosomal subunits are separated and return to the cytoplasmic pool. The details of the **mechanism of protein synthesis** are discussed in Chapter 3. Ribosome-like structures may also be observed within the nucleus, presumably representing various types of RNA.

The Mitochondria

Although the mitochondria were first observed in light microscopy in the latter part of the 19th century, their structure and function have become better known only within the last 50 years. These organelles are present in all eukaryotic cells. Mitochondria are **small, usually elongated structures**, usually less than 0.5 μm in width and less than 7 μm in length. Even within the same cell, the mitochondria may **vary substantially in size and configuration**, assuming spherical, cigar-, club-, or tennis racquet-like shapes. However, the basic **structure** of a mitochondrion, initially described by Palade in 1953, is uniform. Each mitochondrion is **composed of two membranes, located one within the other**. The outer shell of the mitochondrion is a continuous, closed-unit membrane. Running parallel to the outer membrane is a morphologically similar **inner membrane** that forms numerous crests or invaginations (**cristae mitochondriales**), subdividing the interior of the organelle into a series of communicating compartments (Fig. 2-21 and see Frontispiece and Fig. 2-15). Frequently, the cristae are approximately at a right angle to the long axis of the mitochondrion, but they may also be oblique or, for that matter, longitudinal. There is no

P.37

known relationship between the orientation of the cristae and the function of the organelle. A homogeneous material or **mitochondrial matrix**, containing a mixture of molecules and enzymes, fills the interior of the organelle.

Figure 2-19 Active Golgi complex. Electron micrograph of a human labial salivary gland. Note the enormous accumulation of mucous granules (MG) within the Golgi complex (GC) and above it, toward the lumen (L) of the acinus. The basic structure of the Golgi complex is maintained. C = cell (plasma) membrane (see Fig. 2-18). ($\times 8,700$.) (Courtesy of Dr. Bernard Tandler, Sloan-Kettering Institute for Cancer Research, New York.)

The size and configuration of the mitochondria may vary according to the nutritional status of an organ. For instance, the mitochondria of the liver may become very large in some deficiency states, only to return to normal with resumption of a normal diet. Mitochondrial enlargement may also be caused by poor fixation of material. The latter is the probable background of a cell change known as *cloudy swelling* to light microscopists.

Accumulation of fat, hemosiderin, and proteins may be observed in the immediate vicinity of the mitochondria. This probably occurs because of the role of the mitochondria in **energy-producing oxidative processes**. Indeed, the key role of the mitochondria within the cell is that of carriers of energy-producing complex enzyme systems. Several oxidative systems have

been identified within the mitochondria: Krebs cycle enzymes, fatty acid cycle enzymes, and the enzymes of the respiratory chain, including the cytochromes. Most importantly, the formation of energy-producing adenosine triphosphate (ATP) from phosphorus and adenosine diphosphate (ADP) takes place within the mitochondria. The ATP is exported into the cytoplasm where it serves as an essential source of energy for the cell.

It has been documented that the **mitochondria possess their own DNA** that is independent of nuclear DNA and is responsible for independent protein synthesis and for the **mitochondrial division cycle**. This supports the concept that the mitochondria are quasi-independent organelles, living in symbiosis with the host cell, which they supply with energy. It is a matter for an interesting

P.38

speculation that mitochondria may represent **primitive bacteria** that, at the onset of biologic events, became **incorporated into the primordial cell**, and this association became permanent for mutual benefit. Thus, **two genetic systems exist within a cell**, one vested in the mitochondria and the other in the nucleus. The two systems are interdependent, although the exact mechanisms of this association are not understood.

Figure 2-20 Ultrastructural features of a calcitonin-producing medullary carcinoma of the thyroid. Numerous electron-opaque secretory granules bound by a single membrane may be noted (arrowheads). The peripheral cisternae of the Golgi complex (G) show accumulation of electronopaque substance; hence, the assembly of the secretory granules is probably a function of the Golgi apparatus. ($\times 54,400$.) (Koss LG. Morphology of cancer cells. *In* Handbuch der allgemeinen Pathologie, vol. 6, Tumors, part I. Berlin, Springer, 1974, pp 1-139.)

The **mitochondrial DNA** has been extensively studied, and its structure has been determined. It is a small molecule of **double-stranded DNA containing only 37 genes** (13 structural genes encoding proteins, 22 transfer RNA genes, and 2 genes encoding ribosomal RNAs). **All mitochondria of the zygote are contributed by the ovum; hence, all of mitochondrial DNA is of maternal origin.** Because muscle function depends heavily on energy systems

vested in mitochondria, it is not surprising that **various muscular disorders have been observed in association with abnormalities of mitochondrial DNA** (Moraes et al, 1989; Fadic and Johns, 1996; and DiMauro and Schon, 2003). Such disorders are transmitted exclusively by females to their offspring. There is also recent evidence that **mitochondria participate in the phenomenon of programmed cell death or apoptosis**. The issue is discussed at length in Chapter 6.

In **cells characterized by an abundance of mitochondria (oncocytes, sometimes named Hürthle cells, and tumors composed of oncocytes oncocytoomas)**, which may occur in the salivary glands, thyroid, kidney, breast, and sometimes in other organs, the mitochondrial DNA may be modified (Welter et al, 1989). For description of oncocytes and oncocytoomas, see appropriate chapters.

The Lysosomes (Lytic Bodies) and the Autophagic Vacuoles

The lysosomes, or cell **disposal units**, are the organelles participating in the **removal of phagocytized foreign material**. Occasionally, the lysosomes also digest **obsolete fragments**

P.39

of cytoplasm and organelles, such as mitochondria, for which the cell has no further use. The term **autophagic vacuoles** or *residual bodies* has been suggested for such structures. In electron microscopic preparations, the lysosomes may be identified as spherical or oval structures of heterogeneous density and variable diameter (Fig. 2-22). The lysosomes contain several **hydrolytic enzymes**, acid phosphatase being the first one identified, that serve to digest the phagocytized material. It is of interest to note that granules commonly observed in neutrophilic leukocytes belong to the family of lysosomes inasmuch as they contain “packaged” digestive enzymes that assist in the dissolution of phagocytized bacteria.

Figure 2-22 Electron micrograph of epithelial cell, rat urinary bladder. Large oval body containing droplets of dense lipid-like material and clear vesicles. The body is probably a disposal unit and, as such, related to autophagic vacuoles and lysosomes. ($\times 38,000$.)

The origin of at least some lysosomes has been traced to certain regions of smooth endoplasmic reticulum (Novikoff et al, 1973) that is intimately associated with the inner (active) face of the Golgi complex.

It appears that, in some cells at least, the outer membrane of the lysosome may merge with the cell membrane. This is followed by extrusion of the contents of the lysosome into the extracellular space. This process is the reverse of pinocytosis, or phagocytosis (see above).

The lysosomes appear to play an important role in certain **storage diseases**, for example, in **Tay Sachs disease**. This is one of several known inborn or hereditary defects of metabolism wherein the deficiency of an enzyme (hexosaminidase A) results in accumulation of a fatty substance, ganglioside, in lysosome-like vesicles in cells of the central nervous system. In several other uncommon diseases (such as metachromatic leukodystrophy) and certain granulomatous disorders (**malakoplakia**, see Chap. 22), abnormalities of lysosomes play a major role.

The Peroxisomes or Microbodies

The peroxisomal family of organelles is characterized by storage of enzymes involved in **metabolism of hydrogen peroxide**. The most commonly encountered enzyme is catalase. Morphologically, peroxisomes are vesicular structures that, in nonhuman cells, are often provided with a dense **central core** or **nucleoid** (Fig. 2-23). Occasionally, the core has a crystalloid structure. Microbodies were extensively studied in liver cells and cells of the renal proximal convoluted tubules of rats. It has been shown that, under certain circumstances, peroxisomes are capable of becoming very large and, apparently, of dividing (Lavin and Koss, 1973). Whether these organelles have an independent DNA system, such as that of the mitochondria, is not known.

The Centrioles

The centrioles are cytoplasmic organelles that play a key role during cell division. Each interphase animal cell contains a pair of centrioles, short tubular structures, usually located in the vicinity of the concave face of the Golgi complex. As the cell is about to enter mitosis, another pair of centrioles appears, and each pair travels to the opposite poles of the cell and becomes the **anchoring point of the mitotic spindle**. The formation of the mitotic spindle from microtubules is described below.

The origin of the second pair of centrioles has not been fully clarified; apparently it is synthesized *de novo* from precursor

P.40

molecules in the cytoplasm (Johnson and Rosenbaum, 1992). This event is induced and directed in an unknown fashion by the original pair of centrioles. Each pair of centrioles is surrounded by a **clear zone, the centrosome**, which, in turn, is surrounded by a slightly denser area or the **astrosphere**. Within each pair, the centrioles are placed at right angles to each other. Thus, in a fortuitous electron micrograph, one centriole will appear in a longitudinal section and the other in cross section. In the cross section, each **centriole appears as a cylindrical structure with a clear center and nine triplets or groups of three microtubules** (Fig. 2-24). Thus, **the basic structure of the centriole, first described by de Harven and Bernhard in 1956, closely approximates that of cilia and flagella** (see Figs. 2-9 and 2-10). It has been suggested that the centrioles are at the origin of cilia. If this were the case, it would indicate that the centrioles might multiply manifold. It has been observed that formation of the sperm flagellum takes place from one of the centrioles, while the other remains inactive.

Figure 2-23 Peroxisomes (P) or microbodies in proximal tubules of rat kidney. Note the central dense core or nucleoid. Ly = lysosomes; MV = microvilli. ($\times 19,800$.) (Lavin P, Koss LG. Effect of a single dose of cyclophosphamide on various organs in the rat. IV. The kidney. Am J Pathol 62:169, 1971.)

The Cytoskeleton

The skeleton of the cells and, hence, the structures maintaining their physical shape, facilitating their motion, and providing structural support to all cell functions, is provided by a **family of fibrillar proteins**. Several techniques were developed that allow the isolation of these proteins and the production of specific **monoclonal or polyclonal antibodies** that can be used to identify these proteins and to localize them within cells. By techniques of molecular biology, the precise composition of such proteins has been determined and the genes responsible for their formation identified and sequenced (see Chap. 3). This work is not only of theoretical value but has also led to strides in immunocytochemistry, particularly relative to intermediate filaments (see below and Chap. 45).

The cytoskeleton is fundamentally composed of **three types of fibrillar proteins**, initially classified by their diameter in electron microscopic photographs: the **actin filaments** (microfilaments, tonofilaments), **intermediate filaments**, and **microtubules**. They will be described in sequence.

Actin Filaments (Microfilaments, Tonofilaments)

The ubiquitous actin filaments, measuring **5 to 7 nm in diameter**, are observed in all cells of all vertebrate species. In electron microscopy, they can be recognized as **bundles of longitudinal cytoplasmic filaments** crisscrossing the cytoplasm and often converging on specific targets such as desmosomes (see Fig. 2-13). The actin filaments are found within virtually all structural cell components and **interact with many other proteins that regulate their length**. The fundamental structure of these elongated fibrillar proteins is helical, with two different ends: this latter feature allows the filaments to attach to two different molecules and function as an intermediary polarized link. The actin filaments are **easily polymerized** (i.e., they form structures composed of several actin units). This is probably the mechanism that allows actin filaments to form tight meshworks in conjunction with other proteins. Among the latter, it is important to mention

P.41

the **links of actin filaments to a contractile protein, myosin**, accounting for motion and contractility of cells and of cell appendages such as cilia and flagella. Other linkages occur with **transmembrane proteins**, such as spectrin, ensuring the communications between the cell membrane and cell interior. Thus, actin microfilaments perform several essential functions within cells as linkage filaments coordinating the activity of divergent cell components.

Figure 2-24 Centrioles. Electron micrograph of thymus of DBA mouse. Two centrioles are seen in this electron micrograph: one (C) in cross section, showing nice triplets of tubules, and the other (C') in oblique section and apparently at a right angle to (C). Centriole satellite (S) is attached to C'. This may represent the point of anchorage of the tubules of the mitotic spindle. N = nucleus; NM = nuclear membrane. ($\times 94,000$.) (Courtesy of Dr. Etienne de Harven, Sloan-Kettering Institute for Cancer Research, New York.)

Intermediate Filaments

The group of cytoplasmic filaments was initially identified in electron microscopy because of their **diameter (7 to 11 nm)**; hence, intermediate filaments (IFs) are larger than actin microfilaments and smaller than microtubules (see the following section). This group of filaments assumed an important role in immunocytochemistry and histochemistry as **markers of cell derivation and differentiation** by means of **specific antibodies** that serve to identify the presence and the distribution of IFs in cells and tissues (see Chap. 45). The genes governing the synthesis of IFs have been identified by molecular biology techniques and applied to studies of cell differentiation across species, documenting that these genes belong to the fundamental cellular genes in primitive multicellular organisms, such as worms, mollusks, and perhaps even plants (Nagle, 1988 and 1994). It is of interest, though, that the **precise function of the IF proteins is obscure**, as they do not appear to participate in any life cycle events.

Several subspecies of IF proteins have been identified, differing from each other by relative molecular mass (M_r) and anatomic distribution (Table 2-1). Their significance in immunocytochemistry is discussed in Chapter 45. Perhaps the best known of the IFs are the **keratins**, which have been extensively studied in the epidermis of the skin (Sun et al, 1984; Franke et al, 1989). As shown in Figure 2-25, there are several subfamilies of keratin filaments (proteins) forming pairs, each composed of one basic and one acidic protein (see Fig. 2-25A). Each type of squamous epithelium (skin, cornea, other epithelia) may be represented by a special pair of proteins of high relative molecular mass. With the change of epithelial type from a single layer to multilayer epithelium, different keratin genes, producing proteins of increasing

molecular mass are activated (see Fig. 2-25B). This mechanism may be important in understanding the change known as *squamous metaplasia* (see Chap. 6).

Of note is the identification of **lamins**, structural proteins of the nucleus, and its components. These proteins contribute to the **formation of the nuclear membrane and the nuclear pore complexes**. They may play a role in the organization of interphase chromosomes (see below).

Microtubules

Microtubules, measuring between **22 and 25 nm in diameter**, have long been recognized and identified by light microscopy as the **constituents of the mitotic spindle**. The determination of their existence in the interphase cells required

P.42

electron microscopy. The understanding of their chemical makeup, function, and molecular biology is an ongoing process. Microtubules are **hollow, tube-like structures**, which appear to be universally present in all cells, and are synthesized from precursor molecules of **tubulin**. As described earlier (see Figs. 2-9 and 2-10), **microtubules are an integral component of cilia, flagella, and centrioles** (see Fig. 2-24). Microtubules, like actin filaments (see above), are polarized, that is, they have one “minus” and one “plus” end; hence, they can be attached to two different molecules and form a bridge between them.

TABLE 2-1 CHARACTERISTICS AND DISTRIBUTION OF INTERMEDIATE FILAMENTS (IF) IN TISSUES

Type	M _r (daltons)	Tissue Distribution
Keratins		
Form: acid types 9-19	40,000-68,000	Epithelia (specific types associated with specific epithelial types and their maturation)
Pairs: neutral - basic types 1-8		
Desmin	53,000	Muscle fibers of all types
Vimentin	57,000	Cells of mesenchymal origin and some epithelial cells, such as mesothelium, thyroid, endometrium
Glial fibrillary proteins (GPF)	55,000	Glial cells, Schwann cells
Neurofilaments	68,000; 160,000; 200,000	Dendrites and axons; body of neuronal cells

Lamins	60,00-80,000	Form nuclear skeleton and various nuclear structures; similar to cytoplasmic IF
--------	--------------	---

For further discussion of intermediate filaments, see Chapter 45.

Modified with permission from Nagle RB. Intermediate filaments: A review of the basic biology. Am J Surg Pathol, 12 (Suppl. 1): 4-16, 1988.

Figure 2-25 A. A unifying model of keratin expression. Keratins of subfamilies A (acidic) and B (basic) are arranged vertically, according to their relative molecular mass (molecular weights). The drawing indicates that keratin proteins of A and B type form pairs, with proteins of increasing relative molecular mass (M_r) making their appearance as epithelia mature from simple to stratified. K = kilodaltons; s.e. = stratified epithelia. B. A schematic drawing showing the embryonic development as well as the postulated evolutionary history of human epidermis. The bottom part of the drawing shows a simplified diagram of electrophoretic analysis of keratins of increasing M_r , expressed in kilodaltons (numbers on right) corresponding to the evolution of epithelia from simple to stratified to keratinized. K = kilodaltons; s.e. = stratified epithelium. (Sun TT, et al. Classification, expression, and possible mechanisms of evolution of mammalian epithelial keratins: A unifying model. In Levin AJ, et al (eds). Cancer Cells, vol. 1. Cold Spring Harbor, New York, Cold Spring Harbor Laboratory, 1984, pp 169-176.)

The principal role for microtubules and associated proteins

P.43

is their **participation in cellular events requiring motion**. Cilia and flagella are a good example of this function in which microtubules perform a sliding movement in association with a protein, dynein, and an energy-producing system, adenosine triphosphate (ATP).

The **mitotic spindle** is synthesized by the cells undergoing mitosis from molecules of tubulin. The **spindle formation may be inhibited** by some drugs, such as colchicine and vinblastine,

or enhanced by Taxol, a potent anti-cancer drug, derived from the bark of a tree, the western yew (*Taxus brevifolia*). These drugs are commonly used in experimental work involving cell division. During cell division, **the centrioles serve as an organizing center for the mitotic spindle** (see above). From the centrioles, located at the opposite poles of the cell, the microtubules attach to the condensed double chromosomes arranged at the metaphase plate (see Chap. 4) and participate in the migration of the single chromosomes into the two daughter cells. Once the mitosis is completed, the spindle microtubules are depolarized and redistributed in the cytoplasm. Undoubtedly, microtubules perform yet other functions within the cell: they may be associated with movements of coated pits and pinocytotic vesicles to and from cell membranes and are associated with cell motion.

Storage of Products of Cell Metabolism Within the Cytoplasm

The identification of the many varied materials produced and stored within the cells was successfully accomplished before the era of electron microscopy. The identification of **lipids, glycogen, mucin, and pigments**, such as bile, hemosiderin, melanin, and lipofuscin, goes back to the 19th century. Electron microscopy has shed considerable light on their ultrastructure, the mechanisms of accumulation, and their relationship to various cytoplasmic organelles. Thus, lipids often accumulate in close rapport with mitochondria (see above). The role of the Golgi complex in the production of mucus and other cell products, and in formation of storage vesicles, was discussed above. The production of various **polypeptide hormones** in the pancreatic islet cells and other cells with endocrine function, accumulating in the form of endocrine cytoplasmic vesicles, has been documented (see Fig. 2-20). The histochemical or immunocytochemical **identification of the nature of various cell products** stored in the cytoplasm may play a **crucial role in diagnosis** of some cell and tissue disorders. As an example, the presence of mucin may be of value in the differential diagnosis of an adenocarcinoma, whereas the presence of melanin may establish the diagnosis of a malignant melanoma. The identification of specific hormones by immunocytochemistry is often of assistance in classifying tumors with endocrine function (see Chap. 45).

The Cytoplasmic Matrix

The space within the cytoplasm, not occupied by the membranous system, the cell skeleton, or by the organelles, is referred to as the *cytoplasmic matrix*. The matrix is composed of **proteins and free ribosomes**. There is still little knowledge about the makeup of the proteins constituting the bulk of the cytoplasmic matrix. It is quite certain that the matrix contains all of the **amino acids necessary for protein synthesis**, various **forms of RNA, and enzymes** (see Chap. 3). Under the impact of various chemicals or heat, the matrix may be irreversibly **coagulated; this is the principle of cell fixation**. In electron micrographs, the matrix appears as a homogeneous substance, occasionally containing fine granules, fibrils, or filaments.

The Nucleus and Its Membrane

The Nuclear Membrane

The nucleus is enclosed within the nuclear membrane, or **nuclear envelope**, composed of **two electron-dense membranes**, each measuring approximately 75 Å in thickness and separated from each other by a clear zone measuring from 200 to 400 Å in width. On the **inner (nuclear)** side of the nuclear membrane, there is a **layer of filaments (fibrous lamina)**, about 300 Å in thickness, which presumably enhances the resilience of the membrane and may play a

role in the anchorage of chromosomes. The **outer membrane** of the nuclear membrane resembles rough endoplasmic reticulum because numerous ribosomes are attached to it; thus, it may be considered as a part of the cell's inner membrane system. The nuclear membrane is characterized by the presence of **nuclear pores** (Fig. 2-26). A pore is an area where there is a **fusion of the two dense layers of the nuclear envelope**. A complex array of protein molecules with a central channel, about 9 nm in diameter (**nuclear pore complex**), constitutes the nuclear pore. The nuclear pores serve as **exchange channels between the nucleus and the cytoplasm**. Freeze-fracture of the nuclear membrane discloses that the **distribution of the nuclear pores is random** and does not follow any geometric pattern (Fig. 2-27). Still, the nuclear pores form a close relationship with individual chromosomes and their **number may be chromosome dependent**. For example, it has been shown that the number of nuclear pores is increased in aneuploid cancer cells with elevated DNA content and, hence, elevated number of chromosomes (Czeriak et al, 1984). This is in keeping with the new data on the organization of the normal interphase nucleus (see below). The nuclear membrane **disappears during the late prophase** of the mitosis and is **reformed during the late telophase** (for stages of mitosis, see Chap. 4). The probable mechanism of formation of the nuclear membrane is discussed below.

The intact nuclear envelope shows a **remarkable resistance to trauma** or corrosive chemicals such as acids or alkali. When a cell is exposed to such agents, the cytoplasm usually disintegrates fairly rapidly, but the nuclear envelope usually remains intact, protecting the contents of the nucleus. **This remarkable property of the nuclear envelope is utilized in many techniques of nuclear isolation**, for example, in measuring DNA content by flow cytometry (see Chap. 47).

The Nucleus

The nucleus is the principal repository site of DNA and, therefore, is the **center of events governing metabolic and**

P.44

reproductive processes of the cell. The basic concepts pertaining to the mechanism of DNA structure and function are described in Chapter 3. The events in cell division (cell cycle and mitosis) are described in Chapter 4.

Figure 2-26 Area of nucleus. Electron micrograph of an epithelial cell, rat bladder; N = nucleus. Note the nuclear envelope, consisting of two membranes, the inner (IL) and the outer (OL), separated by a translucent space. The inner (nuclear) aspect of the nuclear membrane appears thick because of the presence of a fibrous lamina. Nuclear pores (NP) are well in evidence. Nuclear contents appear granular; CY = cytoplasm. ($\times 64,000$.)

Resting or Interphase Nucleus

In light microscopy of appropriately stained preparations, the “**resting**” or **interphase nuclei** of normal cells are seen as a **large, usually spherical structure** located within the cytoplasm. In stained preparations, the nucleus is surrounded by a **distinct, thin peripheral ring, representing the nuclear membrane**. The **location** of the nucleus depends on cell shape: in cells of approximately spherical, oval, or spindly configuration, the nucleus usually occupies a central position; in cells of columnar shape, which are usually polarized, the nucleus is frequently located in the vicinity of the distant cell pole, away from the lumen of the organ. The **shape** of the normal nucleus may vary: it is usually spherical but may be oval, elongated, or even indented, and, hence, kidney-shaped, depending on cell type. In **polymorphonuclear leukocytes and megakaryocytes**, the nuclei form two or more lobes. Located **within the nucleus** is an important organelle, the **nucleolus**, which may be single or multiple (see below).

The dominant **chemical component** of the interphase nucleus is a **mixture of DNA and associated histones and nonhistone proteins (known in the aggregate as nuclear chromatin)** that readily reacts with dyes such as hematoxylin, that confer upon the nucleus a bluish stain of variable intensity (see Frontispiece and Fig. 2-1).

The **double-stranded DNA** within the nucleus can also be stained with a highly specific stain, the **Feulgen stain** (Fig. 2-28), which is extensively used in quantitative analysis of DNA. The total DNA can also be visualized and quantitated with the use of **specific fluorescent reagents (probes)**, such as **propidium iodide or DAPI**, extensively

P.45

used in molecular biology and quantitative and analytical cytology (see Chap. 47).

Figure 2-27 Freeze-fracture replica of the nuclear membrane of a urothelial cell, showing random distribution of the nuclear pores (*arrows*) on face E and face P. Note the fine granules of intermembrane proteins in the background. (Approx. $\times 50,000$.) (Courtesy of Dr. Bogdan Czerniak.)

Figure 2-28 Feulgen-stained cultured malignant cells from an experimental carcinoma of the bladder (line BC 7, probably fibroblastic). The stain is specific for double-stranded DNA; hence, only the nuclei are stained. Note the increase in the intensity of staining of the condensed chromosomal DNA in the mitotic figures. ($\times 1,000$.) (Culture by Dr. Fritz Herz, Montefiore Hospital. Koss LG. Morphology of cancer cells. *In* Handbuch allgemeinen Pathologie, vol. 6, Tumors, part I. Berlin, Springer, 1974, pp 1-139.)

The **size of the nucleus** depends substantially, but not absolutely, on its **DNA content**. During the cell cycle, described in Chapter 4, the **DNA content of the nucleus doubles during the synthesis phase (S-phase) and remains double until the cell divides**. The **diameter of nuclei with a double amount of DNA is about 40% larger** than that of nuclei in the resting phase of the cell cycle. Thus, the assessment of the nuclear size, an important feature in recognition of cancer cells, must always be compared with a population of normal cells. For further discussion of this issue, see Chapter 7.

In well-fixed and stained cells, within the homogeneous background of the nucleus (sometimes referred to as nuclear “sap”), one can observe a fine network of thin, thread-like linear condensations, known as the **linin network**. Located at various points in the network are small, dark **granules of odd shapes, the chromocenters**. The chromocenters are composed of an **inactive form of DNA**, composed of sequences that do not participate in the biologic activities; therefore, they are designated as **constitutive heterochromatin**. Constitutive heterochromatin may also be identified in chromosomal preparations around the centromeres (see Chap. 4). This form of chromatin should be distinguished from **another form of condensed chromatin**

that may occur in only some cells and that is called facultative

P.46

heterochromatin. An example of the latter is the **sex chromatin body** (also known as the **Barr's body** after the person who described it), which is a condensed portion of one of the two X chromosomes and, therefore, is seen only in females or male individuals with genetic abnormalities, such as excess of X chromosome (Klinefelter's syndrome) (see Chaps. 4 and 9 for further discussion of this condition). The **sex chromatin body is seen as a triangular dark structure, attached by its base to the inner side of the nuclear membrane, with the tip of the triangle pointed toward the center of the nucleus.** The identification of the sex chromatin body is of value in the recognition of some genetic disorders and occasionally cancer cells (see Chaps. 7, 26, and 29).

Interphase Nucleus in Electron Microscopy

Except for the nuclear membrane, described above, the ultrastructure of the interphase nucleus does not cast much light on its organization. The area of the nucleus is filled with finely granular material, or **nuclear "sap" (nucleoplasm)**, wherein one can observe scattered ribosomes. The filamentous proteins, lamins, may sometimes be observed as a network of fine filaments attached to the nuclear membrane. The **chromatin** may be seen as **overlapping electron-dense or dark areas at the periphery of the nucleus**, undoubtedly representing **fragments of chromosomes** attached to the nuclear membrane (see below—structure of interphase nucleus). The correlation of the electron microscopic images with specific chromosomes has been poor, even with the use of immunoelectron microscopy, wherein specific genes or proteins can be identified by antibodies usually labeled with colloidal gold.

The Nucleus in Cycling Cells

In a cell population that is proliferating and, therefore, is characterized by mitotic activity, the appearance of the nonmitotic nucleus may change. Besides the **enlargement**, caused by the increase in DNA during the **S-phase of the cell cycle** (see above), the granularity of the nucleus may increase substantially during the **prophase of the mitosis because of early condensation of parts of chromosomes** in the form of chromatin granules. Although such events are more common in cancer cells (see Chap. 7), they may also occur in normal cells undergoing cell division.

The Nucleolus

In a normal interphase resting nuclei, the nucleoli are seen as **round or oval structures of variable sizes**, averaging about 1 μm in diameter, occupying a small area within the nucleus. The location of the nucleoli is variable but, in light microscopy, they are usually located close to the approximate center of the nucleus, rarely at the periphery. The **number of nucleoli per nucleus** varies from one to four but usually only one nucleolus is observed. The reason for the variable number of nucleoli is their **origin in the nucleolar organizer loci, located on each of the two homologues of chromosomes 13, 14, 15, 21, and 22.** Thus, theoretically, 10 nucleoli per cell should be seen. However, the small nucleoli merge shortly after the birth of the cell, thus reducing the total number of these organelles.

Thanks to the work of Caspersson and his colleagues in Sweden (1942, 1950), much is known about the **natural sequence of events in the life of a nucleolus.** The nucleoli are born within the nucleolar organizer loci in the designated portion of the chromosomes by accumulation of proteins and **ribonucleic acid (RNA)**, which "explodes" the center of the

chromosomal fragment (Figs. 2-29 and 2-30). The **chromosomal DNA of the nucleolus organizing locus forms a rim surrounding the RNA-rich central space and is easily recognized as the nucleolus-associated chromatin**. After merger of small nucleoli, the larger nucleolus, or nucleoli, occupies a central role in the life of a cell as the center of production of RNA (see Chap. 3). The nucleolus disappears at the onset of cell division, only to be reborn again in the daughter cells after mitosis.

The **size of the nucleoli** in interphase cells **varies according to the function of the cell**. In metabolically active cells, such as cells processing or secreting various products, the nucleoli are larger than in quiescent cells with limited metabolic activities. For example, in mucus-secreting intestinal epithelial cells, the nucleoli are larger than in squamous cells, which perform an essentially passive protective function. Under some circumstances, such as an **injury requiring rapid repair** when the cells are forced to produce a large amount of protein, the **accumulation of large amounts of RNA causes the nucleoli to become multiple and very large** and measure up to 4 or 5 μm in diameter. Large nucleoli of irregular configuration are common in cancer cells (see Chap. 7).

An important feature of the nucleoli in light microscopy is their **staining affinities**. The **center** of the nucleolus accepts **acidophilic dyes**, such as eosin, and therefore stains red. The periphery, that is, **the nucleolus-associated chromatin**, retains the staining features of DNA and, therefore, stains **blue with basophilic dyes**. In Feulgen stains, the nucleolus-associated chromatin accepts the dye, but the center of the nucleolus remains unstained.

The Nucleolus in Electron Microscopy

The ultrastructure of the nucleolus has been extensively studied because of its role as the center of production of RNA (see Chap. 3). The nucleolus is composed of electron-dense and electron-lucent areas. Occasionally, at the periphery of the nucleolus, a distinct dense zone corresponding to the nucleolus-organizing region of a chromosome may be distinguished. The core of the nucleolus corresponds to the granular and fibrillar products of ribosomal RNA in various stages of synthesis.

Organization of the Interphase Nucleus

Although the light microscopic structure and ultrastructure of the nucleus have been well known for many years, as summarized above, until the 1980s, no tools were available to probe the organization of the interphase nucleus. It was commonly thought that during interphase, the nuclear chromatin represented uncoiled chromosomal DNA, forming a structure of incredible complexity. Although individual

P.47

genes could be identified and localized on individual chromosomes by molecular biologic techniques (see Chap. 3), the overall organization of the interphase nucleus remained a mystery. On the other hand, considerable knowledge was accumulated in reference to the nucleus during mitosis, giving rise to the study of cytogenetics (see Chap. 4). Thus, it became known that the normal human cell contains **46 chromosomes, arranged in 22 pairs of nonsex chromosomes or autosomes and two sex chromosomes, either 2 X (in females) or XY (in males)**. Thus, each chromosome had its double and both are known as **homologues**.

Figure 2-29 Diagram of development of nucleolus from nucleolus-associated chromatin. (Caspersson TO. Cell Growth and Cell Function-A Cytochemical Study. New York, WW Norton, 1950.)

The introduction of **fluorescent probes**, first to specific segments of individual chromosomes and then to whole chromosomes, has now allowed us to study the **position and configuration of chromosomes in interphase cells**. The techniques are known as **fluorescent in situ hybridization (FISH)**, and **chromosomal “painting”** techniques. A number of initial studies, conducted mainly on human cells in culture, suggested that, contrary to previous assumptions, individual chromosomes could be identified in interphase cells.

However, only a recent study of terminally differentiated human bronchial cells (Koss, 1998) could document that **all chromosomes retain their identity during the interphase** (Fig. 2-31). Further, it was shown that the **two homologues of the same chromosome were located in different portions of the nucleus and were in close apposition to the nuclear membrane**. By measuring angles formed by two homologues, it could be documented that the **position of individual chromosomes in interphase cells is constant** and is probably maintained in normal cells throughout the entire cell cycle. It was also documented that, in the bronchial cells, the **configuration of the two homologues was somewhat different**, suggesting that they may participate differently in cell function, as has been previously documented for X chromosome (Lyon's hypothesis, see Chap. 4). These studies strongly suggest that the **fundamental organization of the nuclear DNA is orderly throughout the life of the cell** and explains the orderly transmission of the genetic material from one generation of cells to another. The peripheral position of the chromosomes on the nuclear membrane also strongly suggested that **each homologue might be responsible for the formation of its own proprietary segment of the nuclear membrane** during the telophase. It was also suggested that the **nuclear pores**, which are the portals of exit (or entry) of the nuclear products (such as RNA) into the cytoplasm, might be formed at the points of junction of adjacent segments of the nuclear

P.48

membrane. The consequences of these observations may have a significant impact on our understanding of nuclear structure and function.

Figure 2-30 Actual photographs of development of nucleolus inside the nucleolus-associated chromatin in a neurocyte (Feulgen stain). (Caspersson TO. Cell Growth and Cell Function-A Cytochemical Study. New York, WW Norton, 1950.)

Figure 2-31 The position and configuration of chromosomes in terminally differentiated bronchial cells (oval nuclei) or goblet cells (spherical nuclei) stained with FISH. The two homologues of each chromosome are clearly located in different territories of the nucleus. The location of the autosomes on or adjacent to the nuclear membrane is evident. Identification numbers of chromosomes and the sex of the donor (F or M) are indicated. Only one signal was generated for the X chromosome in a male (XM). The differences in configuration and size of territories of the two autosomes (one “compact” and one “open”) are best seen in chromosomes 1F, 1M, 5M, 5F, 7F, 8F, 9M, 10F, 12F, 15M, 20F, and XF. Similar differences were noted for other chromosomes but are not well shown.

The Basement Membrane

The basement membrane is a complex structure that occurs at the **interface of epithelia and**

the underlying connective tissue. There are several component parts to the basement membrane. Best seen in the electron micrograph is a thin, condensed, usually uninterrupted electron-opaque layer, known as **basal lamina** (see Figs. 2-5 and 2-14). Basal lamina is separated from the epithelial cell membranes by a narrow, electron-lucent layer known as **lamina lucida**. Crossing the lamina lucida are the cell junctions, known as **hemidesmosomes**, described above, that anchor epithelial cells to the basal lamina (see above and Fig. 2-14). On the side of the connective tissue, the basal lamina is in close contact with **collagen fibrils**. Basal lamina is also observed in nonepithelial tissues, for example, surrounding **smoothmuscle cells**. Within recent years, the basement membranes have been the subject of intensive studies, for several reasons. The basement membranes are a product of interaction between the epithelial cells and the connective tissue; hence, they form a barrier that has been shown to be important in a variety of diseases. Cell surface receptor molecules, known as **integrins**, are an important factor in regulating the relationship of the cells to the extracellular matrix (Giancotti and Ruoslahti, 1999). Some examples of diseases affecting the basement membrane are disorders of the renal glomeruli, certain skin disorders, and invasive cancer. **Cancer cells**, even in invasive or metastatic cancers, **are capable of reproducing the basal lamina**, although it may be functionally deficient.

The principal functions of the basement membrane appear to be the support and anchorage of cells, such as epithelial cells, and, most likely, a regulatory role in the activity of some other cells, such as the smooth muscle. **Basal lamina also serves as a template in epithelial regeneration.** Major **chemical components** of the basement membrane include several complex proteins, such as laminins, collagen types IV and V, fibronectin, proteoglycans, and other adhesion molecules. The interrelationship of these components with each other, and the cells that produce it, is complex and not fully understood at this time. The relationship of cancer suppressor genes with various adhesion molecules and, hence, the basement membrane, in the genesis of benign tumors and formation of metastases in malignant tumors, is discussed in Chapters 3 and 7.

How Cells Function: Fundamental Concepts of Molecular Biology*

Molecular biology is a branch of the biologic sciences that attempts to explain life and its manifestations as a series of chemical and physical reactions. The critical event that led to the development of this new science was the discovery of the fundamental **structure of deoxyribonucleic acid (DNA)** by Watson and Crick in 1953. Few prior developments in biology have contributed so much and so rapidly to our understanding of the many fundamental aspects of cell function and genetics. Although, so far, the impact of molecular biology on diagnostic cytology has been relatively modest, this may change in the future. Therefore, some of the fundamental principles of this new science are briefly summarized. The main purpose of this review is to describe the events in DNA replication, transcription, and translation of genetic messages; to clarify the new terminology that has entered into the scientific vocabulary since 1953; and to explain the techniques that are currently used to probe the functions of the cell. It is hoped that this review will enable the reader to follow future developments in this still expanding field of knowledge. Of necessity, this summary touches upon only selected aspects of molecular biology, representing a personal choice of topics that, in the judgment of the writer, are likely to contribute to diagnostic cytology. For reasons of economy of space, with a very few exceptions, the names of the many investigators who contributed

P.54

to this knowledge are not used in this text. Readers are referred to other sources listed in the bibliography for a more detailed record of individual contributors and additional information on specific technical aspects of this challenging field.

Molecular biology is easily understood because it is logical and based on the simple principles of organic chemistry. Hence, basic knowledge of organic chemistry is necessary to understand the narrative. Every attempt has been made to tell the story in a simple language.

THE CELL AS A FACTORY

Although the main morphologic components of the cell have been identified by light and electron microscopy (see Chap. 2), until 5 decades ago, the understanding of the mechanisms governing cell function has remained elusive and a matter for conjecture. Molecular biology has now shed light on some of these mechanisms, although, at the time of this writing (2004), much remains to be discovered. The living cell is best conceived as a **self-contained miniature factory that must fulfill a number of essential requirements necessary to manufacture products, either for its own use or for export** (Fig. 3-1). A cell is a three-dimensional structure contained within the **cell membrane**, which is a highly sophisticated, flexible structure (see Chap. 2). The membrane not only protects the cell from possible hostile elements

or environmentally unfavorable conditions, but it is also capable of **selective intake of materials that are important and necessary to the survival of the cell**; this latter property is vested in specialized molecular sites: **the membrane receptors** (see Chap. 2). The cell exports finished products by using intricate mechanisms in which the cell membrane is an active participant. The membrane is also provided with a series of devices, such as **cell junctions**, which allow the cell to live in harmony and to communicate with its neighbors.

The cell is constructed in a sturdy fashion, thanks to the **cell skeleton** composed of microfilaments, intermediate filaments, and microtubules (see Chap. 2). The cell is capable of producing the components of its own skeleton and of regulating their functions. The **energy needs** of the cell are provided by the metabolism of foodstuffs, mainly sugars and fats, interacting with the energy-producing systems, adenosine 5%-triphosphate (ATP), vested primarily in the mitochondria. **The machinery that allows the cell to manufacture or synthesize products for its own use or for export**, mainly a broad variety of proteins, is vested in the system of cytoplasmic membranes, the smooth and rough endoplasmic reticulum, and in the ribosomes (see Chap. 2). **Disposal** of useless or toxic products is vested in the system of **lysosomes** and related organelles. As a signal advantage of most cells over a manmade factory, the cell is

P.55

provided with a **system of reproduction** in its own image, in the form of **cell division or mitosis** (see Chap. 4). Thus, aged and inadequately functioning cells may be replaced by daughter cells, which ensure the continuity of the cell lineage, hence of the tissue, and

ultimately of the species. The equilibrium among cells is also maintained by a **mechanism of elimination of unwanted or unnecessary cells** by a process known as **apoptosis, or programmed cell death**. Apoptosis plays an important role during embryonal development, wherein unnecessary cells are eliminated in favor of cells that are needed for construction of tissues or organs with a definite function. Apoptosis also occurs in adult organisms and may play an important role in cancer. The mechanisms of apoptosis are complex and consist of a cascade of events, involving the mitochondria and the nuclear DNA, discussed at length in Chapter 6.

It is quite evident from this brief summary that a highly sophisticated system of organization, which will coordinate its many different functions, must exist within each cell. Furthermore, within multicellular organisms, these functions vary remarkably from cell to cell and from tissue to tissue; hence, they must be governed by a flexible mechanism of control. The **dominant role in the organization of the cell function is vested in the DNA**, located in the cell's nucleus. The mechanisms of biochemical activities directed by DNA and the interaction of molecules encoded therein is the subject of this summary.

DEOXYRIBONUCLEIC ACID (DNA)

Background

The recognition of the microscopic and ultrastructural features of cells and their fundamental components, such as the nucleus, the cytoplasm with its organelles, and the cell membrane, all described in Chapter 2, shed little light on the manner in which cells function. The key questions were: How does a cell reproduce itself in its own image? How are the genetic characteristics of cells inherited, transmitted, and modified? How does a cell function as a harmonious entity within the framework of a multicellular organism?

The facts available to the investigators during the 100 years after the initial observations on cell structure were few and difficult to reconcile. The developments in organic chemistry during the 19th century documented that the **cells are made up of the same elements as other organic matter, namely, carbon, hydrogen, oxygen, nitrogen, phosphorous, calcium, sulfur**, and very small amounts of some other inorganic elements. Perhaps the most critical discovery was the synthesis of urea by Wöhler in 1828. Soon, a number of other organic compounds, such as various proteins, fats and sugars, were identified in cells. Of special significance for molecular biology was the observation that **all proteins are composed of the same 20 essential amino acids**. A further important observation was that most **enzymes**, hence substances responsible for the execution of many chemical reactions, **were also proteins**. The cell ceased to be a chemical mystery, but it remained a functional puzzle.

The observations by the Czech monk, Gregor Mendel (or Mendl), who first set down the laws governing **dominant and recessive genetic inheritance** by simple observations on garden peas, opened yet another pathway to molecular biology. Was there any possible link between biochemistry and genetics? The phenomenon of mitosis, or cell division, and the presence of chromosomes were first observed about 1850, apparently by one of the founding fathers of contemporary pathology, Rudolf Virchow. Several other 19th-century observers described chromosomes in some detail and speculated on their possible role in genetic inheritance, but, again, there was no obvious way to reconcile the chromosomes with the genetic and biochemical data.

In 1869, a Swiss biochemist, Miescher, isolated a substance from the nuclei of cells from the

thymus of calves, named **thymonucleic acid**, and since renamed **deoxyribonucleic acid or DNA**. The relationship between DNA and the principles of genetic inheritance, as defined by Mendel, was not apparent for almost a century. A hint linking the chromosomes with the “thymonucleic” acid was provided by Feulgen and Rossenbach, who, in 1924, devised a DNA-specific staining reaction, which is known today as the **Feulgen stain**. It could be shown that chromosomes stained intensely with this stain (see Fig. 2-28). Interestingly, in the 1930s, the Swedish pioneer of cytochemistry, Torbjörn Caspersson, suggested that thymonucleic acid could be the substance responsible for genetic events in the cell.

It was not, however, until 1944 that Avery, MacCarty, and MacLeod, working at the Rockefeller Institute in New York City, described a series of experiments documenting that **DNA was the molecule responsible for morphologic changes in the bacterium, *Diplococcus pneumoniae***, thus providing firm underpinning to the principle that the genetic function was vested in this compound. The universal truth of this discovery was not apparent for several more years, particularly because bacterial DNA does not form chromosomes. The understanding of the mechanisms of the function of DNA had to await the discovery of the fundamental structure of this molecule by Watson and Crick in 1953. For a recent review of these events, see Pennisi (2003).

Structure

DNA was once described as a “fat, cigar-smoking molecule that orders other molecules around.” In fact, the molecule of **DNA is central to all events occurring within the cell**. In bacteria and other relatively simple organisms not provided with a nucleus (**prokaryotes**), the DNA is present in the cytoplasm. In higher organisms (**eukaryotes**), most of the DNA is located within the nucleus of the cell. In a nondividing cell, the DNA was thought to be diffusely distributed within the nucleus. Recent investigations, however, strongly suggest that even in the nondividing cells, the chromosomes retain their identity and occupy specific territories within the nucleus (Koss, 1998). For further details of the nuclear structure, see Chapter 2. During cell division, the DNA is condensed into visible chromosomes (see Chap. 4). Small amounts of DNA are also present in other cell organelles, mainly in the mitochondria; hence, the suggestion

P.56

that mitochondria represent previously independent bacterial organisms that found it advantageous to live in symbiosis with cells (see Chap. 2). To understand how DNA performs the many essential functions, it is important to describe its structure. **DNA forms the well-known double helix**, which can be best compared to an ascending spiral staircase or a twisted ladder (Fig. 3-2). The staircase has a supporting external structure, or **backbone**, composed of molecules of a pentose sugar, **deoxyribose**, bound to one another by a molecule of **phosphate**. This external support structure of the staircase is organized in a highly specific fashion: the organic rings of the sugar molecules are alternately attached to the phosphate by their 5' and 3' carbon molecules* (Fig. 3-3). This construction is fundamental to the understanding of the **synthesis of nucleic acids, which always proceeds from the 5' to the 3' end, by addition of sugar molecules in the 3' position**. The **steps of the staircase** (or rungs of the ladder) are **formed by matching molecules of purine and pyrimidine bases**, each attached to a molecule of the sugar, deoxyribose, in the backbone of the molecule (Fig. 3-4; see Fig. 3-2). The purines are **adenine (A)** and **guanine (G)**; the pyrimidines are **thymine (T)** and **cytosine (C)**. It has been known since the 1940s, thanks to the contributions of the chemist, Chargaff, that in all DNA molecules, regardless of species of origin, the proportions of adenine and thymine on the one hand, and of guanine and cytosine on the other

hand, were constant. This information, combined with data from x-ray crystallography of purified molecules of DNA, allowed Watson and Crick to construct their model of the DNA molecule. In it, the purine, adenine, and the pyrimidine, thymine (the **A-T bond**), and cytosine and guanine (the **C-G bond**) are always bound to each other. The triple C-G bond is stronger than the double A-T bond (see Figs. 3-2 and 3-4). This **relationship of purines and pyrimidines is immutable**, except for the **replacement of thymine by uracil (U) in RNA** (see below), and is the basis of all subsequent technical developments in the identification of matching fragments of nucleic acids (see below). The term **base pairs (bp)** is frequently used to define one matching pair of nucleotides and to define the length of a segment of double-stranded DNA. Thus, a DNA molecule may be composed of many thousands of base pairs. It is of critical importance to realize that the sequence of the purine-pyrimidine base pairs varies significantly, in keeping with the encoding of the genetic message, as will be set forth below.

Figure 3-3 Schematic representation of the backbone of DNA and the direction of synthesis from 5' to 3', indicating positions of carbons in the molecules of sugar.

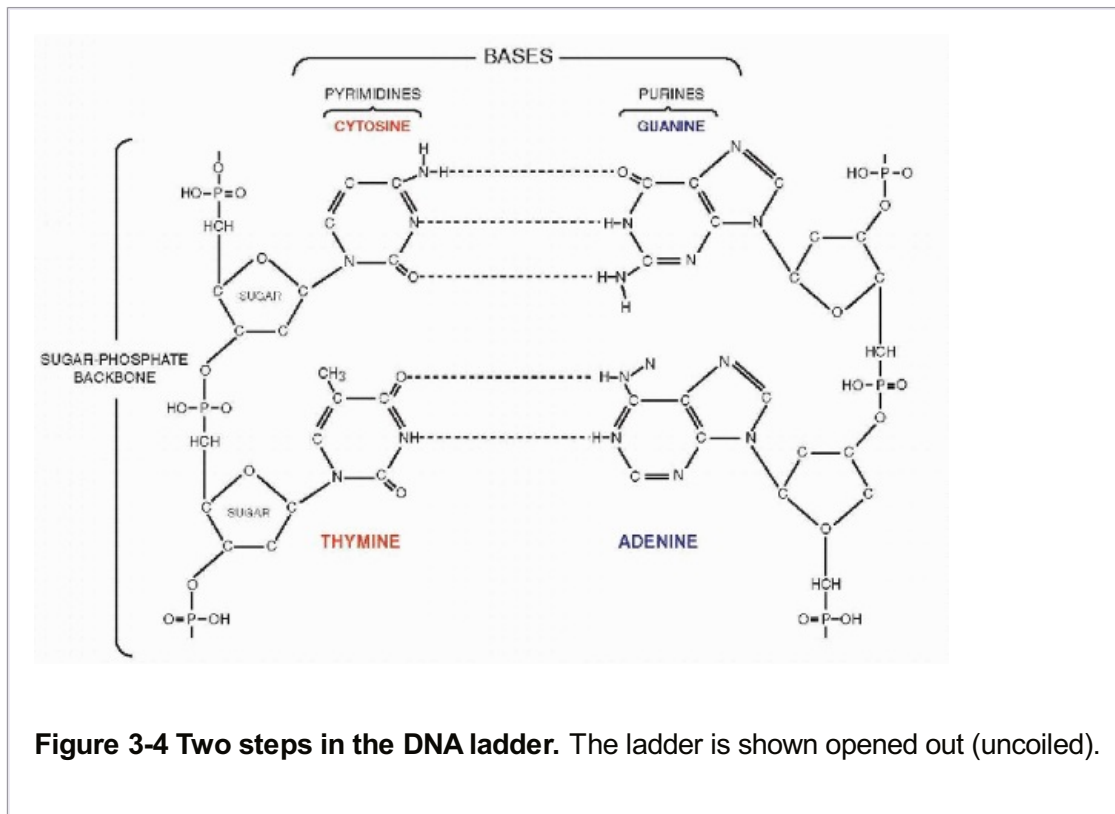

Packaging

DNA is an enormous molecule. If fully unwrapped, it measures about 2 meters in length (but only 2 nm in diameter) in each single human nucleus. Each of the 46 individual human chromosomes contains from 40 to 500 million base pairs and their DNA is, therefore, of variable length, but still averages about 3 cm. It is evident, therefore, that to fit this gigantic molecule into a nucleus measuring from 7 to 10 μm in diameter, it must be folded many times. The **DNA is wrapped around nucleosomes**, which are cylindrical structures, composed of proteins known as *histones* (see Fig. 4-5). This reduces the length of the molecule significantly. Further reduction of the molecule is still required, and it is assumed that DNA forms multiple coils and folds to form a compact structure that fits into the space reserved for the nucleus. An apt comparison is with a wet towel that is twisted to rid it of water and then folded and refolded to form a compact ball. The interested reader is referred to a delightful book by Calladine and Drew (1997) that explains in a simple fashion what is known today about packaging of DNA. Be it as it may, individual chromosomes are

P.57

composed of multiple coils of DNA, as shown in Figure 4-5 and discussed at some length in

Chapter 4.

**Replication**

The elegance and simplicity of the structure of the double helix resolved the secret of inheritance of genetic material. Because the double helix is constructed of two reciprocal, matching molecules, it was evident to Watson and Crick that **DNA replication can proceed in its own image**: the double helix can be compared to a zipper, composed of two corresponding half-zippers. Each half of the zipper, or one strand of DNA, serves as a template for the formation of a mirror image, complementary strand of DNA (Fig. 3-5). Hence, the first event in DNA replication must be the separation of the two strands forming the double helix. The precise mechanism of strand separation is still not fully understood, although the enzyme primase plays an important role. A further complication in the full understanding of the mechanisms of DNA replication is that the DNA molecule is wrapped around nucleosomes (see above). How the nucleosomal DNA is unwrapped and replicated, or for that matter transcribed (see below), is not fully understood as yet.

The synthesis of the new strand, governed by enzymes known as **DNA polymerases**, follows the fundamental principle of A-T and G-C pairing bonds and the principle of the 5'-to-3' direction of synthesis, as described above. Because the two DNA strands are reciprocal, the synthesis on one strand is continuous and proceeds without interruption in the 5'-to-3' direction. The synthesis on the other strand also follows the 5'-to-3' rule but must proceed in the opposite direction; hence, it is discontinuous (Fig. 3-6). The segments of DNA created in the discontinuous manner are spliced together by an enzyme, ligase. When both strands of DNA (half-zippers) are duplicated, two identical molecules (fullzippers) of DNA are created. This fundamental basis of DNA replication permits the daughter cells to inherit all the characteristics of the mother cell that are vested in the DNA. Replication of DNA takes place during a well-defined period in a cell's life, the **synthesis phase or S-phase of the cell cycle, before the**

onset of cell division (mitosis) (see Chap. 4). By the time the cell enters the mitotic division, the DNA, in the form of chromosomes; is already duplicated. Each chromosome is composed of two identical mirror-image DNA segments (chromatids), bound together by a centromere (see Fig. 4-2). It is evident that the mechanism of DNA replication is activated before mitosis, when the chromosomal DNA is not visible under the light microscope, because the chromosomes are markedly elongated.

The exact sequence of events leading to the entry of the cell into the mitotic cycle is still under investigation and may be influenced by extracellular signals (see review by Cook, 1999).

Whatever the mechanism, a family of proteins, **cyclins**, causes the resting cell to enter and progress through the phases of the cell division. For a review of cyclins, see the article by Darzynkiewicz et al (1996) and Chapter 4.

It is also known that the **replication of the chromosomes**

P.58

is not synchronous and that some of them replicate early and others replicate late. It has been proposed that those genes common to all cells that ensure the fundamental cell functions and “housekeeping” chores, replicate during the first, early part of the S-phase, whereas the tissue-specific genes replicate late. During other phases of the cell cycle, the mechanism of DNA replication is either inactive or markedly reduced.

Figure 3-5 The DNA molecule and its manner of replication. Each base pair and its respective sugar-phosphate helix comes apart and induces synthesis of its complementary chain.

Figure 3-6 Events in DNA replication. Following the 5' to 3' direction of synthesis, one strand replicates in a continuous manner, whereas the complementary second strand replicates in shorter segments that must be bound (spliced) together by the enzyme, ligase.

If one considers that during the lifetime of the human organism, DNA replication occurs billions of times and that even single **errors of replication** affecting critical segments of DNA may result in serious genetic damage that may lead to clinical disorders (see below), it is evident that efficient mechanisms of replication control must exist that will eliminate or neutralize such mistakes. Work on bacteria suggests that there are at least three controlling steps in DNA replication: selection of the appropriate nucleotide by DNA polymerases; recognition of the faulty structure by another enzyme; and finally, the repair of the damage. In eukaryotic cells, the molecule **p53**, which has been named "**the guardian of the genome**," appears to play a critical role in **preventing replication errors** prior to mitosis. As discussed in Chapter 6, cells that fail to achieve DNA repair will be eliminated by the complex mechanism of **apoptosis**. Regardless of the technical details, it is quite evident that these control mechanisms of DNA replication in multicellular organisms are very effective.

Transcription

Once the fundamental structure of DNA became known, attention turned to the manner in which this molecule governed the events in the cell. There were two fundamental questions to be answered: How were the messages inscribed in the DNA molecule (i.e., how was the genetic code constructed?) and how were they executed? It became quite evident that the gigantic molecule of DNA could not be directly involved in cell function, particularly in the formation of

the enzymes and other essential molecules. Furthermore, it had been known that protein synthesis takes place in the cytoplasm and not in the nucleus; hence, it became clear that an intermediate molecule or molecules had to exist to transmit the messages from the nucleus to the cytoplasm (see Fig. 3-8A). The best candidate for this function was **RNA**. RNAs, or the **ribose nucleic acids**, were analyzed at about the same time that the basic chemical makeup of DNA became known, in the 1940s. They were known to **differ from DNA in three respects: the sugar** in the molecule was **ribose**, instead of deoxyribose (hence the name); the molecule, instead of being double-stranded, was **singlestranded** (although there are some exceptions to this rule, notably in some viruses composed of RNA); and the **thymine** was replaced by a very similar base, **uracil** (Fig. 3-7). Several forms of RNA of different molecular weight (relative molecular mass) were known to exist in the cytoplasm and the nucleus. However, they appeared to be stable and, accordingly, not likely to fulfill the role of a messenger molecule that had to vary in length (and thus in molecular mass)

P.59

to reflect the complexity of the messages encoded in the DNA. The molecule that was finally identified as a **messenger RNA, or mRNA**, was difficult to discover because it constitutes only a small proportion of the total RNA (2% to 5%) and because of its relatively short life span. The DNA code is **transcribed** into mRNA with the help of specific enzymes, **transcriptases** (Fig. 3-8A). The transcription, which occurs in the nucleus on a single strand of DNA, follows the principles of nucleotide binding, as described for DNA replication, except that in RNA, thymine is replaced by a similar molecule, uracil (Fig. 3-8B). As will be set forth in the following section, each molecule of mRNA corresponds to one specific sequence of DNA nucleotides, encoding the formation of a **single protein molecule, hence a gene**. Because the size of the genes varies substantially, the mRNAs also vary in length, thus in molecular mass, corresponding to the length of the polypeptide chain to be produced in the cytoplasm. The identification of and, subsequently, the in vitro synthesis of mRNA proved to be critical in the further analysis of the genetic code and in subsequent work on analysis of the genetic activity of identifiable fragments of DNA. For a recent review of this topic, see articles by Cook (1999) and Klug (2001).

Figure 3-7 Fundamental structure of an RNA molecule and its sugar, ribose.

Figure 3-8 A. A diagrammatic representation of the principal nuclear and cytoplasmic events in protein formation. **B.** DNA replication, transcription, and translation for the amino acid methionine and for the stop codons, indicating the beginning and the end of protein synthesis. Note the replacement of thymine (T) by uracil (U) in mRNA. It is evident that the process could be reversed; by unraveling the composition of a protein and its amino acids, it is possible to deduce the mRNA condons, thereby the DNA code for this protein.

Reannealing

In experimental in vitro systems, **the bonds between the two chains of DNA can be broken** by treatment with alkali, acids, or heat. Still, the affinity of the two molecules is such that once the cause of the strand separation is removed, the two chains will again come together, an event known as **reannealing**. These properties of the double-stranded DNA became of major importance in gene analysis and molecular engineering.

MOLECULAR TRAFFIC BETWEEN THE NUCLEUS AND THE CYTOPLASM

Although it has been known for many years that the nucleus is provided with gaps in its membrane, known as the **nuclear pores** (see Chap. 2 and Fig. 2-26), the precise function of the nuclear pores was unknown. Within recent years, some light has been shed on the makeup of the nuclear pores and on the mechanisms of transport between the nucleus and the cytoplasm. The nuclear pores are composed of complex molecules of protein that interact with DNA (Blobel, 1985; Gerace et al, 1978; Davies and Blobel, 1986). Further, specific molecules have been identified that assist in the export of mRNA and tRNA from the nucleus into the cytoplasm and import of proteins from the cytoplasm into the nucleus across the nuclear pores. Proteins, known as **importins** and **exportins** have now been identified as essential to the traffic between the nucleus and the cytoplasm. The interested readers are referred to a summary article by Pennisi (1998) and the bibliography listed.

The Genetic Code

The unraveling of the structure of DNA and its mechanism of replication was but a first step in understanding the mechanism

P.60

of cell function. The subsequent step required deciphering the message contained in the structure. Since neither the sugar molecule nor the phosphate molecule had any specificity, **the message had to be contained in the sequence of the nucleotide bases (i.e., A,G,T, and C)**, as was suggested by Watson and Crick shortly after the fundamental discovery of the structure of the DNA. It was subsequently shown that the **DNA code is limited to the formation of proteins from the 20 essential amino acids**. The specific sequences of nucleotides that code for amino acids could be defined only after the pure form of the intermediate RNA molecules could be synthesized.

By a series of ingenious and deceptively simple experiments, it was shown that **different clusters of three nucleotides coded for each of the 20 amino acids**, the primary components of all proteins. A sequence of three nucleotides, encoding a single amino acid, is known as a **codon** (Fig 3-9B). **A series of codons, corresponding to a single, defined polypeptide chain or protein, constitutes a gene**. As discussed in the foregoing, the code inscribed in the DNA molecule is transcribed into mRNA, which carries the message into the cytoplasm of the cell wherein protein formation takes place (see Fig. 3-8A). The code, therefore, was initially defined, not as a sequence of nucleotides in the DNA, but as it was transcribed into RNA. Because there are four nucleotides in the RNA molecule (A,G,C, and U, substituting for T), and three are required to code for an amino acid, there are $4 \times 4 \times 4$ or 64 possible combinations. These combinations could be established by using synthetic RNA. Thus, the identity of the triplets of nucleotides, each constituting a codon, could be precisely established (see Fig. 3-9). It may be noted that only **one amino acid, methionine, is coded by a unique sequence, AUG** (adenine, uracil, guanine). It was subsequently proven that the **codon for methionine initiated the synthesis of a sequence of amino acids constituting a protein**. In other words, every protein synthesis starts with a molecule of methionine, although this amino acid can be removed later from the final product. All other amino acids are encoded by two or more different codons. There are also three nucleotide sequences that are interpreted as termination or **“stop” codons**. The stop codons signal the end of the synthesis of a protein chain.

GENETIC CODE					
1st position (5')	2nd position				3rd position (3')
	U	C	A	G	
U	Phe	Ser	Tyr	Cys	U
	Phe	Ser	Tyr	Cys	C
	Leu	Ser	<u>Stop</u>	<u>Stop</u>	A
	Leu	Ser	<u>Stop</u>	Trp	G
C	Leu	Pro	etc.		U
	Leu				C
	Leu				A
	Leu				G
A	Met		etc.		U
					C
					A
					G
G			etc.		U
					C
					A
					G

EXAMPLES OF CODONS

CUC leucine	UUU phenylalanine	CCC proline	GGG glycine	AUG methionine
----------------	----------------------	----------------	----------------	-------------------

Figure 3-9 Examples of codons for several amino acids using the first, second, and third position of the mRNA nucleotides, uracil (U), cytosine (C), adenine (A), and guanine (G). It may be noted that 19 amino acids have multiple codes (for example, tyrosine [Tyr] is coded by UAU and UAC). There is but one code for methionine (Met), namely AUG, indicating the beginning of a protein. There are several stop codons, indicating the end of protein synthesis (see Fig. 3-8B).

Once the RNA code was established, it became very simple to identify corresponding nucleotide sequences on the DNA by simply substituting U(racil) by T(hymine). This reciprocity between DNA and RNA base sequences was also subsequently utilized in further molecular biologic investigations (see Fig. 3-8B).

MECHANISMS OF PROTEIN SYNTHESIS OR mRNA TRANSLATION

The unraveling of the genetic code and the unique role of proteins still did not clarify the precise mechanisms of the synthesis of proteins, often composed of thousands of amino acids. It is now known that protein formation,

P.61

or **translation of the message encoded in mRNA**, takes place in the cytoplasm of the cell and requires two more types of RNA. One of these is **ribosomal RNA (rRNA)**, which accounts for most of the RNA in the cell and is the principal component of **ribosomes**. These granulelike organelles are each made up of one small and one larger spherical structure separated by a

groove, thus somewhat resembling a Russian doll (see Fig. 2-17). The third type of RNA is the **transfer RNAs (tRNA)**, which function as carriers of the 20 specific amino acids that are floating freely in the cytoplasm of the cell. For a recent review of this topic, see the article by Cech (2000).

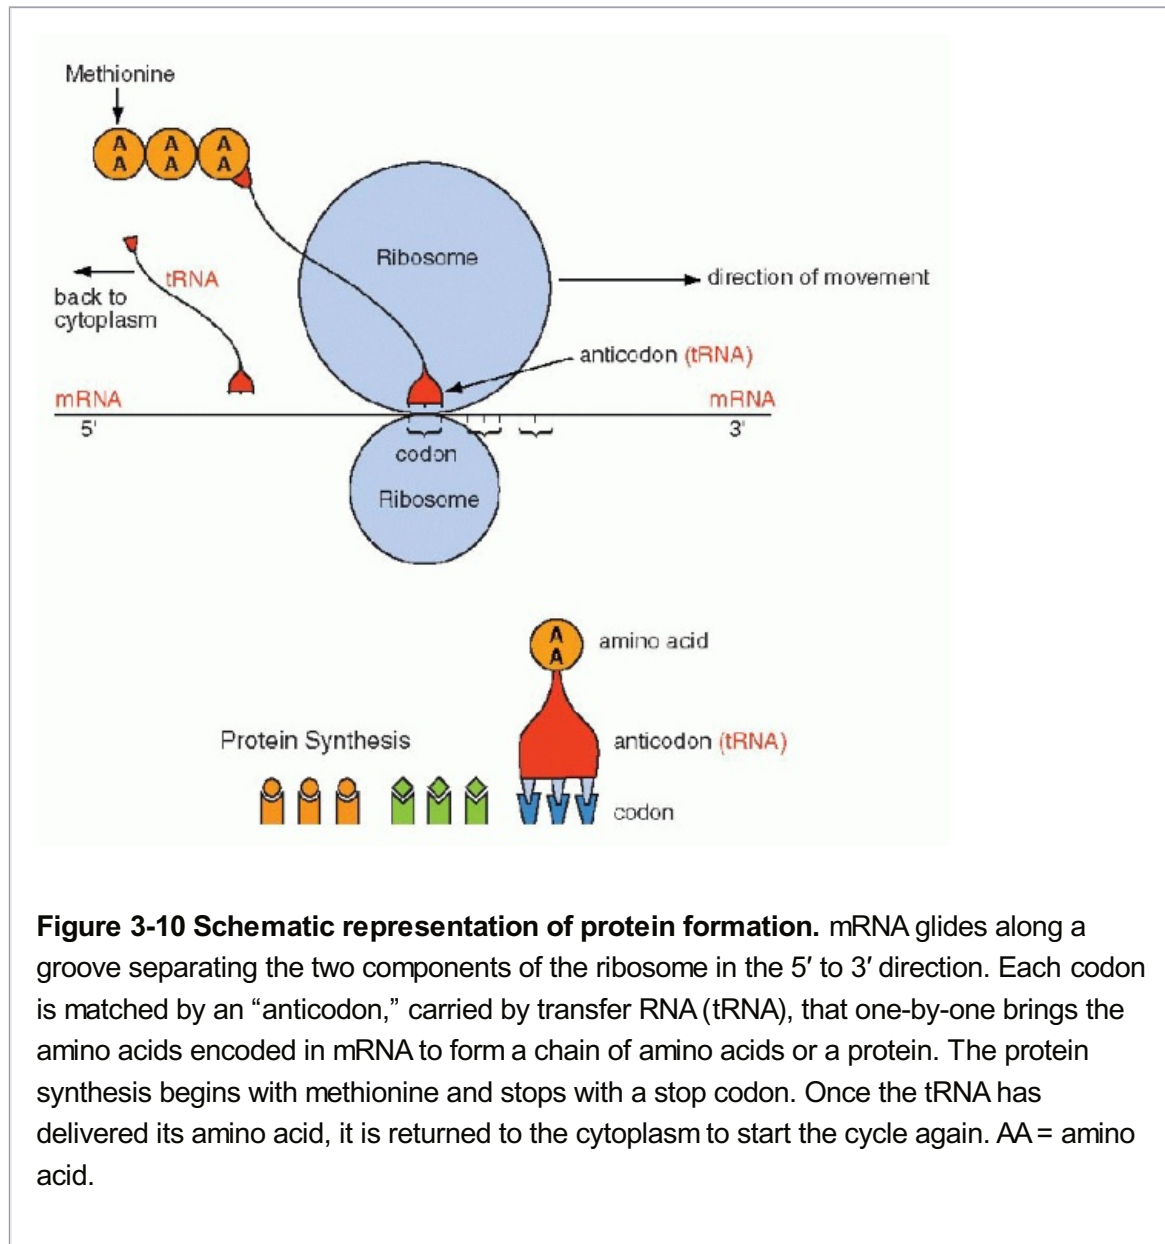

Figure 3-10 Schematic representation of protein formation. mRNA glides along a groove separating the two components of the ribosome in the 5' to 3' direction. Each codon is matched by an “anticodon,” carried by transfer RNA (tRNA), that one-by-one brings the amino acids encoded in mRNA to form a chain of amino acids or a protein. The protein synthesis begins with methionine and stops with a stop codon. Once the tRNA has delivered its amino acid, it is returned to the cytoplasm to start the cycle again. AA = amino acid.

The synthesis of proteins occurs in the following manner: mRNA, carrying the message for the structure of a single protein, enters the cytoplasm, where it is captured by the ribosomes. The synthesis is initiated by the codon for methionine. The mRNA slides along the ribosomal groove, and the **sequential codons are translated one by one into specific amino acids that are brought to it by tRNA**. Each molecule of tRNA with its specific **anticodon sequences that correspond to the codons**, carries one amino acid (Fig. 3-10). In translation, the same principles apply to the matching (pairing) of nucleotides and the direction of synthesis, from the 5' to the 3' end, as those discussed for DNA replication and transcription into mRNA. The amino acids attach to each other by their carboxy (COOH)—and amino (NH)—terminals and form a protein chain. The synthesis stops when a stop codon is reached and the protein is released into the cytoplasm where it can be modified before use or export (Fig. 3-11). The specific sequence of events in translation is currently under intense scientific scrutiny.

It is generally assumed that inaccurate translation results in formation of a so-called nonsense protein that is apparently recognized as such and is either not further utilized or is destroyed.

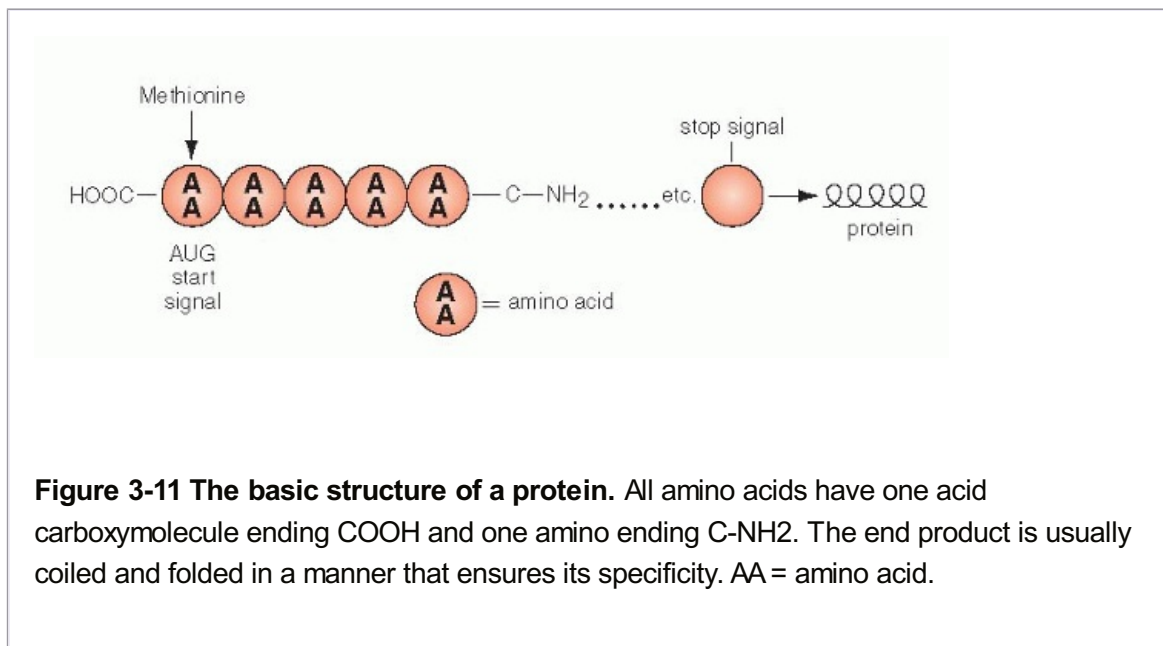

Figure 3-11 The basic structure of a protein. All amino acids have one acid carboxymolecule ending COOH and one amino ending C-NH₂. The end product is usually coiled and folded in a manner that ensures its specificity. AA = amino acid.

UNIQUENESS OF PROTEINS AS CELL BUILDING BLOCKS AND BASIS OF PROTEOMICS

The deciphering of the genetic code led to one inescapable conclusion: The **code operates only for amino acids, hence proteins, and not for any other structural or chemical cell components, such as fats or sugars**. Therefore, proteins, including a broad array of enzymes, are the core of all other cell activities and direct the synthesis or metabolism of all other cell constituents. By a feedback mechanism, the synthesis and replication of the fundamental molecules of DNA or RNA are also dependent on the 20 amino acids that form the necessary enzymes. Proteins execute all events in the cell and, thus, may be considered the plenipotentiaries of the genetic messages encoded in DNA and transmitted by RNA. One must reflect on the extraordinary simplicity

P.62

of this arrangement and the hierarchical organization that governs all events in life.

The recognition of the unique role of proteins in **health and disease** has led to the recently developed techniques of **proteomics**. The purpose of proteomics is the identification of proteins that may be specific for a disease process, leading to development of specific drugs (Liotta and Petricoin, 2000; Banks et al, 2000). Micromethods have been developed that allow **protein extraction and identification** from small fragments of tissue (Liotta et al, 2001).

DEFINITION OF GENES

Once the mechanism of protein formation had been unraveled, it became important to know more about the form in which the message is carried in the DNA. Briefly, from a number of studies, initially with the fruit fly, *Drosophila*, then with the mold, *Neurospora*, it could be demonstrated that each protein, including each enzyme, had its own genetic determinant, called a gene. With the discovery of the structure of DNA and the genetic code, a **gene is defined as a segment of DNA, carrying the message corresponding to one protein or, by implication, one enzyme**. The significance of the precise reproduction of the genetic

message became apparent in 1949, when Linus Pauling and his colleagues suggested that sickle cell anemia, characterized by a deformity of the shape of red blood cells, was a “molecular disease.” The molecular nature of the disease was established some years later by Ingram, who documented that sickling was due to the **replacement of a single amino acid** (hence, by implication, one codon in several hundred) in two of the four protein chains in hemoglobin. This replacement **changes the configuration of the hemoglobin molecule** in oxygen-poor environments, with resulting deformity of the normal spherical shape of red blood cells into curved and elongated structures that resemble “sickles.” More importantly still, sickle cell anemia behaves exactly according to the principles of heredity established by Mendel. If only one parent carries the gene, the offspring has a “sickle cell trait.” If both parents carry the gene, the offspring develops sickle cell anemia.

To carry the implications of these observations still further, if the genes are segments of nuclear DNA, then they should also be detectable on the metaphase chromosomes. With the development of specific genetic probes and the techniques of in situ hybridization, to be described below, the presence of normal and abnormal genes on chromosomes could be documented.

REGULATION OF GENE TRANSCRIPTION: REPRESSORS, PROMOTERS, AND ENHANCERS

Once the principles of the structure, replication, and transcription of DNA were established, it became important to learn more about the precise mechanisms of regulation of these events. If one considers that the length of the DNA chain in an *Escherichia coli* bacterium is about four million base pairs and that of higher animals in excess of 80 million base pairs, these molecules must contain thousands of genes. How these genes are transcribed and expressed became the next puzzle to be solved. Since it appeared that the fundamental mechanisms could be the same, or similar, in all living cells regardless of species, these studies were initially carried out on bacteria, which offered the advantage of very rapid growth under controlled conditions that could be modified according to the experimental needs.

The French investigators, Jacob and Monod, demonstrated that the functions of genes controlling the utilization of the sugar, lactose, by the bacterium *E. coli*, depended on a feedback mechanism. The activation or deactivation of this mechanism depended on the presence of lactose in the medium. It was shown that the transcription of the gene encoding an enzyme (β -galactosidase) that is necessary for the utilization of lactose, is regulated by an interplay between two DNA sequences, the **repressor** and the **operator**. The activation or deactivation of the repressor function is vested in the operator. The repressor function, which prevents the activation of the family of enzymes known as **transcriptases**, is abolished at the operator site by the presence of lactose. In the absence of lactose, the repressor gene is active and blocks the transcription at the operator site. Once the operator gene is derepressed by the lactose, the β -galactosidase gene is transcribed into the specific mRNA by the enzyme, RNA polymerase. The activity of the RNA polymerase is triggered by two sequences of bases located on the DNA molecule, one about 35 and the other about 10 bases **ahead of the site of transcription, or upstream**. These DNA sequences are known as **promoters** and they are recognized by RNA polymerase as a signal that the transcription may begin **downstream**, that is, at the first nucleotide of the DNA sequence (gene) to be transcribed (Fig. 3-12). The promoter is provided with specific, very short nucleotide sequences, or “**boxes**,” which regulate still further the transcription of DNA into mRNA (the discussion of boxes will be

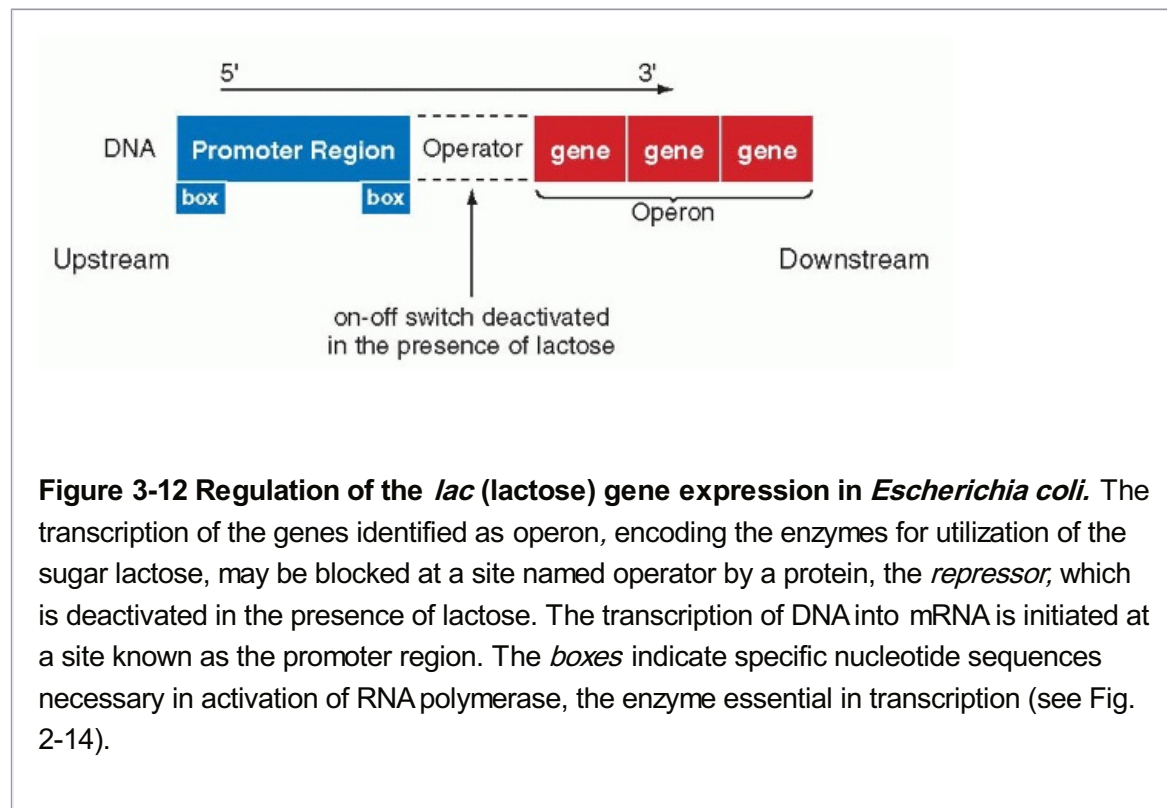

expanded below). The terms *upstream* and downstream have become incorporated into the language of molecular biology to indicate nucleotide sequences located on the DNA either before or after a specified gene or sequence of genes.

In the cytoplasm of the bacterium, the mRNA, which contains the sequences necessary for the transcription of the β -galactosidase, together with two other adjacent genes (providing additional enzymes necessary for utilization of lactose by the bacterium) is transcribed into the three enzymes. The name **operon** was given to a sequence of the three genes that are transcribed into a single mRNA molecule. Subsequently, similar regulatory mechanisms were observed for other genes on prokaryotic cells, confirming the general significance of these observations.

The search for similar mechanisms in eukaryotic cells began soon thereafter. An important difference in mRNA between prokaryotic and eukaryotic cells must be stressed: The mRNA of prokaryotes contains information for several proteins (an operon), whereas the mRNA of eukaryotic cells

P.63

encodes only one protein, an advantage in the manipulation of this molecule.

Promoter sequences were also recognized in DNA of nucleated, eukaryotic cells. In such cells, two sequences of bases are known to occur: one of them is the so-called **CAT box** (a sequence of bases 5'-CCAAT-3', occurring about 80 to 70 bases upstream, and the other, a **TATA box** (a sequence of 5'-TATAAA-3'), occurring about 30 to 25 bases upstream. The RNA polymerase activity begins at base 1, and it continues until the gene is transcribed. The end of the transcription is signaled by another box composed of **AATAA** sequence of bases (Fig. 3-13). At the beginning of the transcription, at its initial or 5' site, the mRNA acquires a "cap" of methylguanidine residues, which presumably protects the newly formed molecule from being attacked by RNA-destroying enzymes (RNAses). At the conclusion of the transcription, the mRNA is provided with a sequence of adenine bases (AAAAA), also known as the **poly-A tail**.

As always, the RNA is transcribed from the 5' end to the 3' end.

Subsequently, other DNA sequences important in the transcription of eukaryotic genes, named enhancers, were also discovered. It is of interest that the enhancer sequences may be located at a distance of several hundred or even several thousand nucleotides from the promoter site. It has been proposed that the enhancer sequences act through DNA loops that may bring together the enhancer site and the gene, thereby facilitating its transcription. Subsequently, the discovery of specific promoter and enhancer sequences of DNA played a major role in molecular engineering (see below).

Exons and Introns

Once the principles of the genetic code were unraveled, it was thought that the transcription of DNA into mRNA was a simple one-on-one process, resulting in a direct copy of the DNA sequence into an RNA message. It was noted first in 1977 that the message contained in DNA genes was, in fact, substantially modified: **the mRNA was often considerably shorter than the anticipated length**, with segments that were removed before RNA left the nucleus. The **removed segments of RNA were called introns**, and their removal required “splicing” or bringing together the **remaining portions of RNA, called exons** (Fig. 3-14).

The presence of introns complicated enormously the sequencing of mammalian genes, because it became evident that large portions of the DNA molecule, although transcribed, carried no obvious message for translation in the cytoplasm. In fact, there is still much speculation but little factual knowledge about the reasons for the existence of introns. It is generally thought that they exercise some sort of a regulatory function in RNA transcription.

Additional studies documented that **only a small proportion (about 5%) of human DNA**

encodes for protein genes. The remaining bulk of the molecule represents **non-coding DNA**. Whether this is an appropriate term for the DNA, with completely unknown function and significance, remains to be seen. It is of interest, though, that in the noncoding DNA, there are repetitive nucleotide sequences (also known as **short tandem repeats, inverted repeats, and interspersed repeats**) that vary from individual to individual and thereby allow **genetic fingerprinting** (see below).

P.64

Figure 3-14 Schematic representation of transcription of mammalian genes. The splicing of the exons is shown in the *bottom* part of the diagram.

REGULATION OF GENE EXPRESSION IN EUKARYOTIC CELLS

Although some of the mechanisms of gene encoding, transcription, and translation have been elucidated, the understanding of the fundamental principles of gene expression in complex multicellular organisms is still very limited. Some progress has been reported in the studies of embryonal differentiation in a small worm, *caenorhabditis elegans*, which has only 19,000 genes that have been sequenced (Ruvkun and Hobert, 1998). Whether these studies are applicable to humans remains to be seen. It is important to realize that a **zygote, composed of the DNA complements of an ovum and a spermatozoon, contains all the genes necessary to produce a very complex multicellular organism**. It is quite evident that, during the developmental process, genes will be successively activated and deactivated until a mature, highly differentiated organism has reached its full development. It is known now that **unneeded cells are eliminated by the process of apoptosis** (see Chap. 6). Still, how these events are coordinated is largely unknown at this time. Here and there, a gene or a protein is discovered that interacts with other genes and proteins and activates or deactivates them. Recently, **double-stranded RNA molecules**, known as *interference RNA (iRNA)*, have been shown to play an important role in gene deactivation (Ashrafi et al, 2003; Lee et al, 2003). These relationships are increasingly complex and constantly changing, suggesting that the **blueprint for gene expression in eukaryotic cells in complex multicellular organisms has not been discovered as yet** and most likely will remain elusive for some time. It could be documented, though, that given appropriate circumstances, **all genes can be found in every**

cell. This has been dramatically documented by **cloning of sheep and other animals using nuclei derived from mature epithelial cells.** Long-suppressed genes can also be activated in instances when growth processes are deregulated, for example, in cancer. It is of interest that certain genetic sequences that are likely to be involved in gene activation appear to be highly preserved (conserved) in all multicellular organisms, including insects, strongly supporting the concept of unity of all life.

If these issues of activation of genes during fetal development may be considered esoteric, there is unfortunately equally limited understanding of gene expression in mature cells. It is known that the transcription of mRNA can occur only off one strand of the DNA molecule. Hence, the separation of the two strands of DNA is an important prerequisite of gene transcription. Clearly, during the normal activity of a mature cell, all active genes necessary for the cell's survival and function must be activated and deactivated at one time or another. It is generally assumed that the separation and reannealing of the DNA strands and gene expression and repression are due to various proteins binding to each other and to specific regions of the DNA, but the precise knowledge of these events currently eludes us.

RESTRICTION ENZYMES (ENDONUCLEASES) AND SEQUENCING OF DNA

Although considerable progress was made in understanding the mechanisms of gene transcription after the discovery of the principles of the genetic code and the repressor-operator system in bacteria, the exact makeup of genes (i.e., the sequence of codons) in eukaryotic cells remained a mystery, largely because of the enormous size of the DNA molecules. Although chemical methods for analysis and sequencing of DNA were known, they shed little light on the arrangement of bases, hence on the genetic code of genes. The discovery of **restriction enzymes (endonucleases)** in the 1970s significantly modified this situation. Restriction enzymes that were capable of breaking down foreign DNA were discovered in bacteria.

It soon became evident that these enzymes were highly specific because they **recognized specific sequences of nucleotides or clusters of nucleotides** and, thus, could be used to cut DNA at specific points. The enzymes were **named after the bacterium of origin.** For example, the bacterium *E. coli* gave rise to the enzyme *EcoRI*, *Bacillus amyloliquefaciens* to enzyme *BamHI*, *Haemophilus influenzae* to enzyme *HindIII*, and so on. These enzymes recognize a sequence of four, six, or eight bases in the corresponding complementary chains of DNA (Fig. 3-15). Because the frequency of sequential four bases is greater than that of six or eight bases, the enzymes recognizing a sequence of four bases will cut the DNA into smaller pieces than the enzymes recognizing a larger number of sequential nucleotides. Moreover, because the two chains of DNA are complementary, they may or may not be cut in precisely the same location. As a consequence, the ends of the DNA fragment of the two chains may be of unequal length, leading to the so-called **sticky ends**, in which one chain of the DNA will be longer than the other. This feature of DNA fragments obtained by means of restriction enzymes is most helpful in recombinant DNA studies (see below).

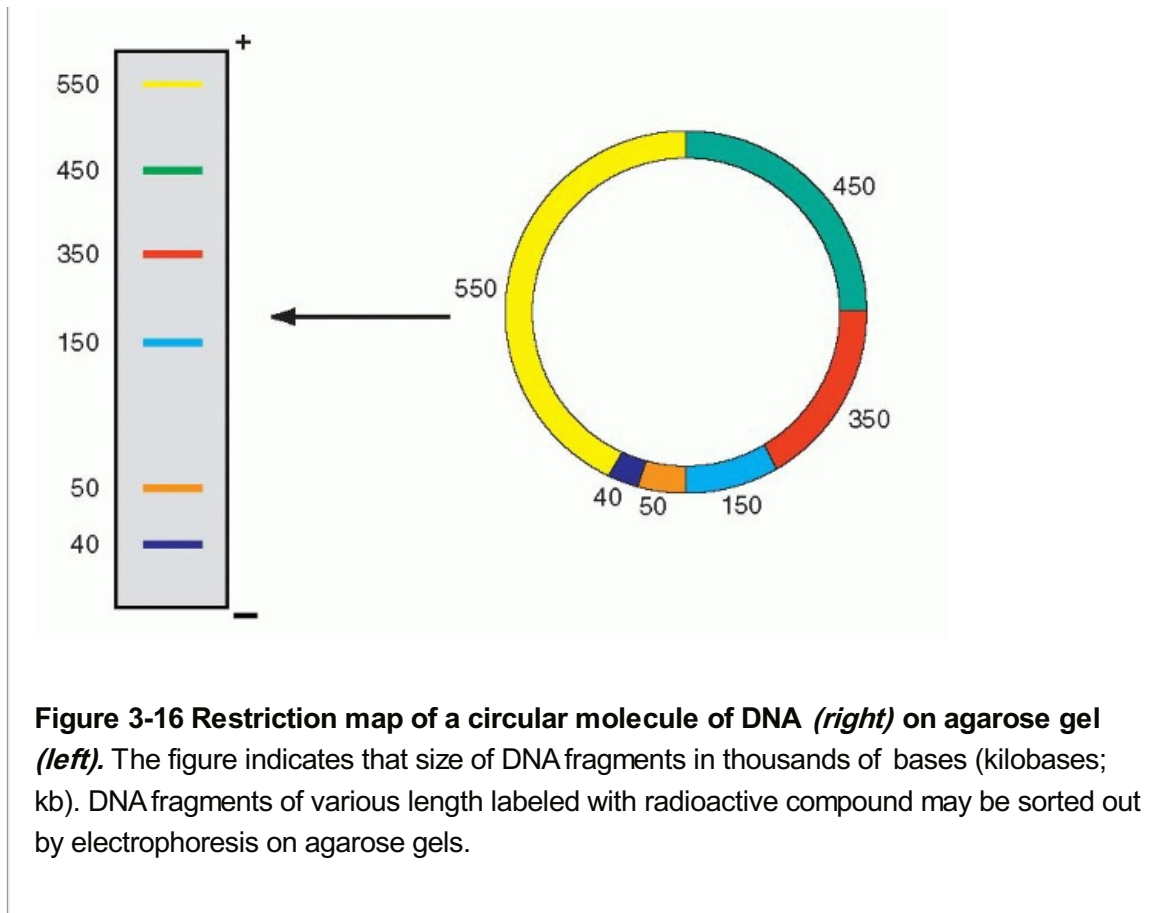

The restriction enzymes were the tools needed to **cut very large molecules of DNA into fragments of manageable sizes** that could be further studied. Perhaps the most important initial observation was that **DNA fragments could be separated from each other by creating an electric**

P.65

field (electrophoresis) in loosely structured gels of the sugar, agarose. The DNA fragments are separated from each other by size, with smaller fragments moving farther in

the gel than larger fragments, and **by configuration**, with circular fragments moving farther than the open fragments of similar length. The fragments can be visualized by **staining with DNA-specific dyes**, such as ethidium bromide, or by radioactive labels that give autoradiographic signals on photographic plates (Fig. 3-16). Thus, a **restriction map** of a DNA molecule can be produced. Each fragment can also be removed intact from the gel for chemical analysis or **sequencing** of bases or transferred onto nitrocellulose paper for **hybridization** studies with appropriate probes (see below). Several methods of analysis of the DNA fragments, known as *base sequencing* were developed, leading to precise knowledge of the sequence of bases. The technical description of sequencing methods is beyond the scope of this summary, and the reader is referred to other sources for additional information. Currently, automated instruments are used for this purpose.

SEQUENCING OF THE ENTIRE HUMAN GENOME

In 2001, simultaneous publications from the International **Human Genome Project** (Lander et al, 2001) and a commercial company, Celera (Ventner et al, 2001), nearly **three billion nucleotide codes**, organized in about **30,000 genes**, became known. The promise of this tedious and time-consuming

P.66

work is the identification of genes and gene products (proteins) specific for disease processes (Collins, 1999; Collins and Guttmacher, 2001; McKusick, 2001; Subramanian et al, 2001; Guttmacher and Collins, 2002; Collins et al, 2003). Because the number of individual proteins is probably in the millions, it is quite evident that each of the $\pm 30,000$ human genes is capable of producing multiple proteins. A number of techniques such as **proteomics** (discussed above) and **microarray techniques** (briefly discussed below and in Chap. 4) address these issues under the global name of **translational research**.

REVERSE TRANSCRIPTASE AND COMPLEMENTARY DNA (cDNA)

As described above, the transcription of the message from DNA to RNA is governed by a family of enzymes, known as *transcriptases*. An important advance in molecular biology was the discovery of the enzyme **reverse transcriptase** by Baltimore and by Temin and Mizutani in 1970, based on observation of replication mechanisms of RNA viruses (**retroviruses**) in mammalian cells. The genetic code of these viruses is inscribed in their RNA and **they cannot replicate without the help of the host cells**. The viruses were shown to carry a nucleotide sequence encoding an enzyme, **reverse transcriptase**, which allows them to **manufacture a single chain of complementary DNA (cDNA) from the nucleotides available in the host cell**. The single-stranded cDNA, which contains the message corresponding to the viral RNA

genome, is copied into a double-stranded DNA by an enzyme, DNA polymerase. This double-stranded DNA molecule is incorporated into the native DNA of the host cell. **The host cell is now programmed to produce new viral RNA.** The viral RNA, upon acquiring a new capsule at the expense of the host membrane, becomes the reconstituted virus, which leaves the host cell to start the reproductive cycle in another cell (Fig. 3-17).

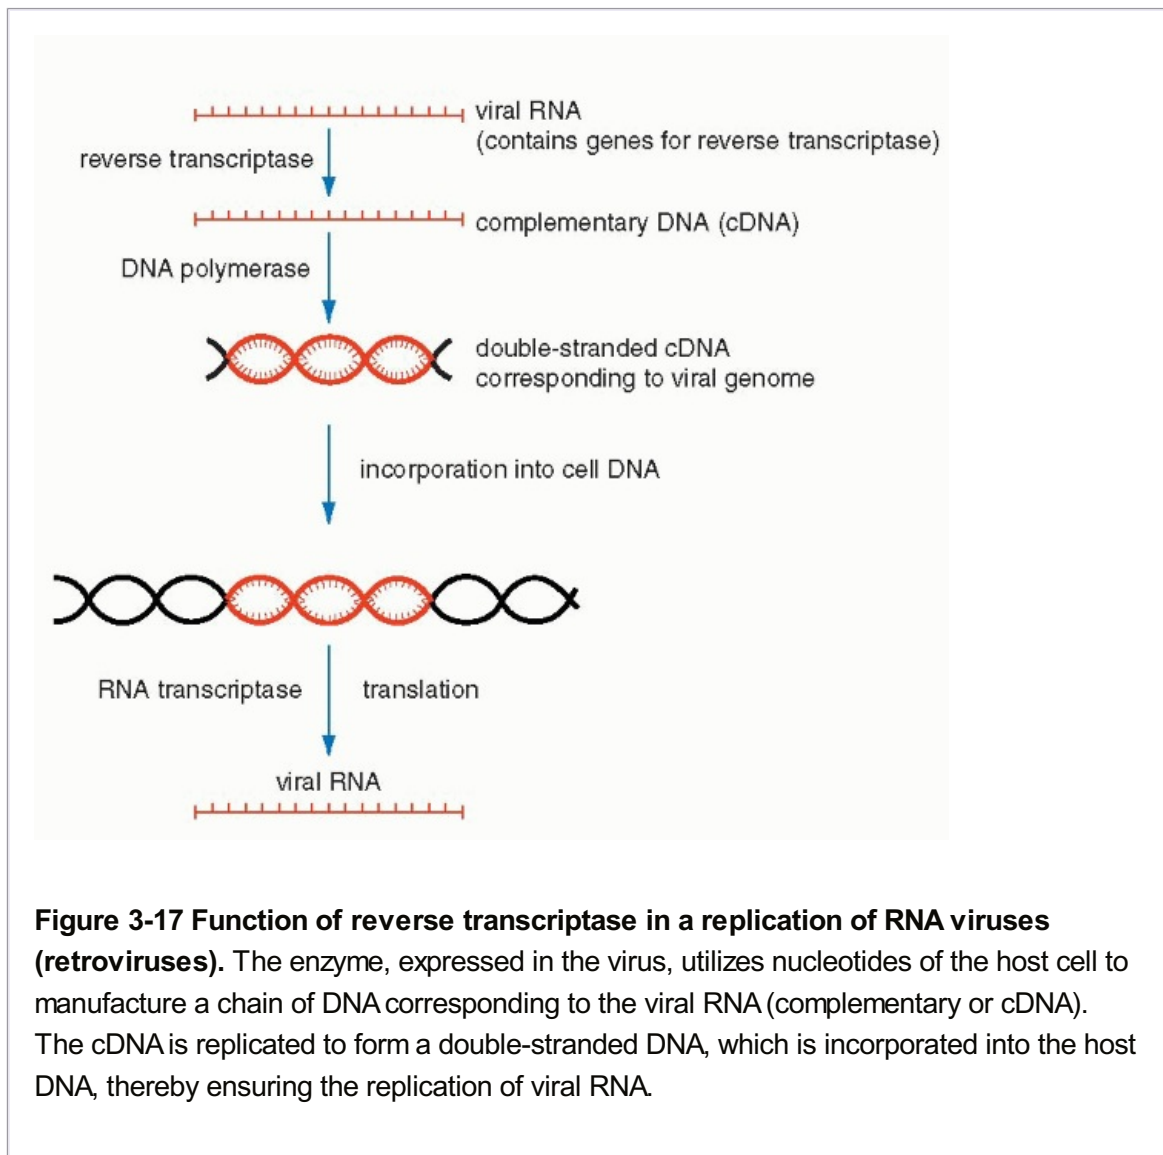

Figure 3-17 Function of reverse transcriptase in a replication of RNA viruses (retroviruses). The enzyme, expressed in the virus, utilizes nucleotides of the host cell to manufacture a chain of DNA corresponding to the viral RNA (complementary or cDNA). The cDNA is replicated to form a double-stranded DNA, which is incorporated into the host DNA, thereby ensuring the replication of viral RNA.

Reverse transcriptase became an extremely important enzyme in **gene identification and replication in vitro**. By means of reverse transcriptase, any fragment of RNA can now be fitted with a corresponding strand of synthetic cDNA, based on the customary principle of matching of nucleotides, described earlier. This fragment of cDNA can be duplicated by DNA polymerase into a double-stranded fragment that can be incorporated into a **plasmid** or other vector for replication in bacteria (see below). Conversely, any fragment of DNA, after separation of the strands, can be matched with synthetic RNA, which can be utilized to produce a single- or double-stranded cDNA by means of reverse transcriptase.

IDENTIFICATION OF GENES

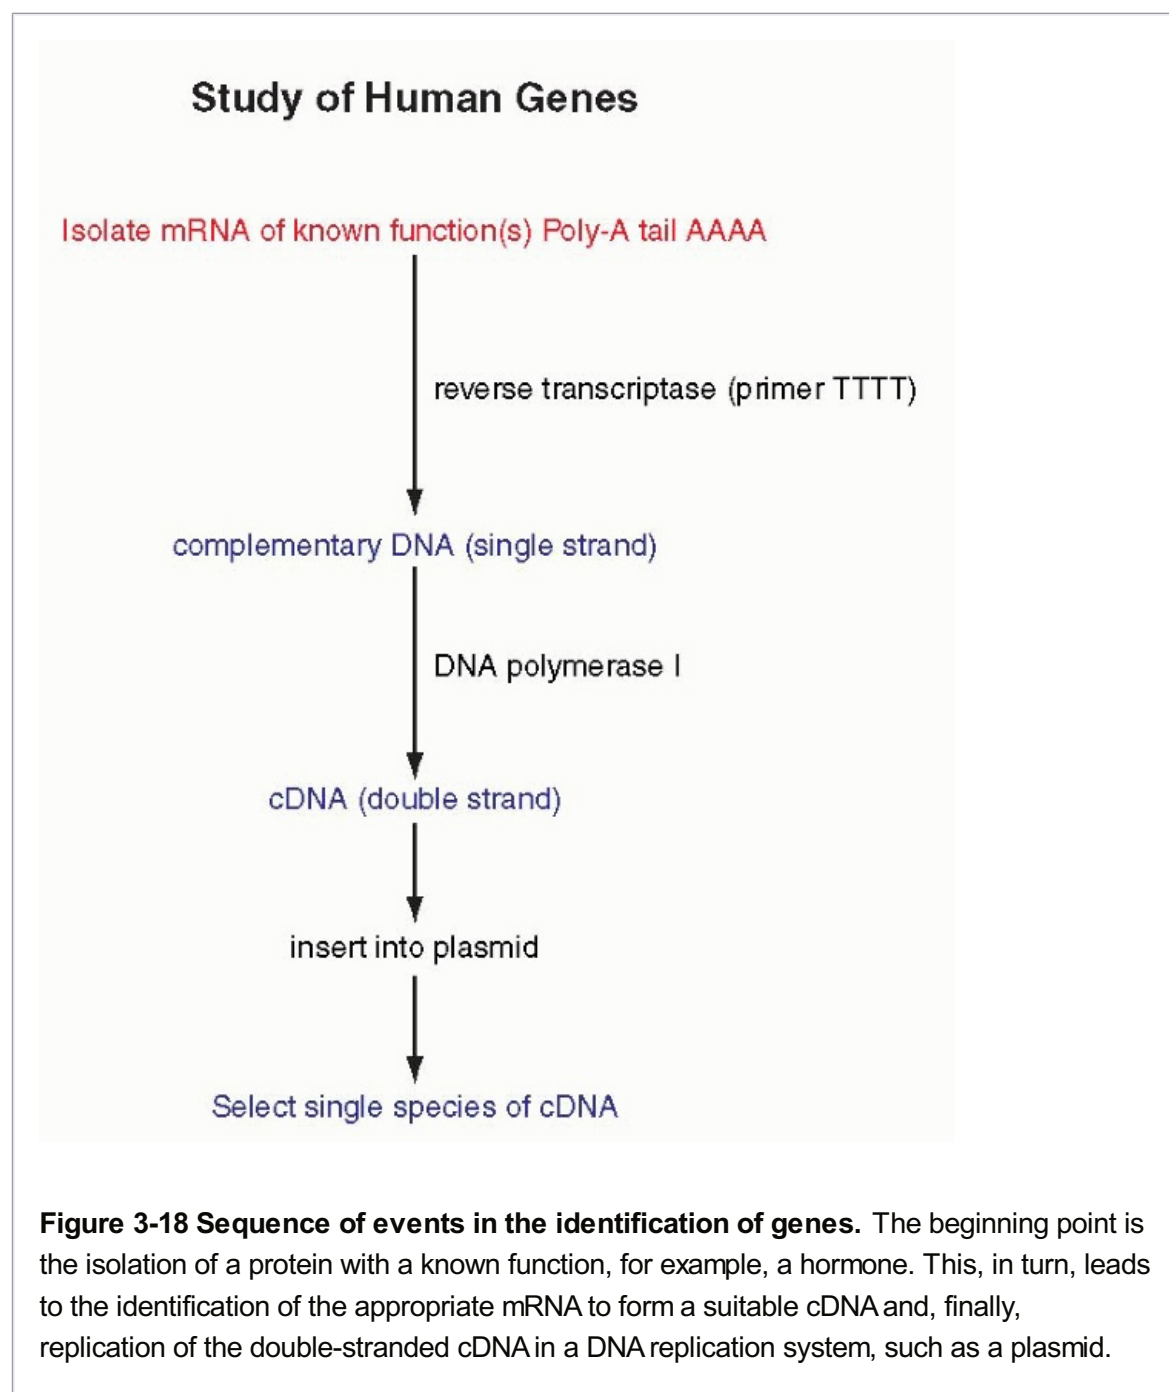

The understanding of the relationship between DNA, mRNA, and proteins has greatly facilitated the task of identifying DNA sequences that code for various cell products. By starting with phages and viruses, and then moving on to eukaryotic cells, the science of identification and

sequencing of genes with a known final product became relatively simple. The starting point can now be a sequence of amino acids in a protein product, such as a hormone. An isolated or synthetic mRNA in the presence of reverse transcriptase and a mixture of nucleotides can be used to construct a segment of the cDNA corresponding to the protein product encoded by the mRNA (Fig. 3-18). Considerable progress in techniques of gene identification has been applied to the Human Genome Project (see above).

The sequencing of nucleotides in a DNA fragment allows a computer-based comparison with other known sequenced genes. Such comparisons enable the identification of genes across various species of eukaryotic cells to determine partial or complete preservation of genes in various stages of evolution. With the use of this technique, it could be shown that certain genes may be common to humans and many other

P.67

species, including insects, suggesting a common ancestry to all multi-cellular organisms.

Computer analysis of sequences of nucleotides also permits the search for genes or DNA sequences, not interrupted by the boxes, indicating the beginning and the end of mRNA transcription. Such uninterrupted sequences of DNA are called **open-reading frames**. Each reading frame encodes an appropriate mRNA and a protein product. Open-reading frames represent a convenient way of presenting genetic components of smaller DNA molecules, such as viruses (see Chap. 11).

DNA CLONING IN VITRO

The concept of reproducing genes, or fragments of genes, in vitro was based on a number of discoveries and technical improvements that have occurred since the late 1970s, most of them briefly summarized in the preceding pages. The ability to separate fragments of DNA by restriction enzymes, their identification, and their sequencing represented the first step in this chain of events. It has been known for many years that bacteria possess not only genetic DNA but also “**parasitic**” DNA, known as **phages and plasmids**. The DNA of these parasitic species replicates within the bacteria, exploiting the machinery of DNA replication belonging to the host cell. The sequencing of phages and plasmids, and their dissection by restriction enzymes, led to a marriage of these methods and to molecular engineering.

It was mentioned previously that some restriction enzymes cut DNA chains in an uneven manner, leaving “sticky” ends. This observation became of capital importance in DNA replication in vitro or for DNA cloning. Thus, it became possible to **insert into a plasmid or phage a piece of DNA from another species**, utilizing the “sticky ends” as points of fusion. The replication in bacteria of the engineered parasitic DNA would ensure that the **DNA insert would also be replicated**. Plasmid DNA particularly proved to be extremely useful because it can be cut with the same enzymes as the DNA of other species, again with formation of sticky ends. A further useful feature of the plasmids was their role in conferring on bacteria resistance to specific antibiotics. It was of particular value that the **plasmid known as pBR322 carried two drug-resistance genes, one to ampicillin and one to tetracycline**. Thus, by inserting a fragment of foreign DNA into the plasmid at the site of one of the resistance genes, this gene is destroyed. By inserting the plasmid into a bacterium, one could expect the plasmid to multiply. However, the growth of the bacteria, hence that of the plasmids and of the foreign DNA, could be controlled by the antibiotics represented by the intact gene (Fig. 3-19). This option proved to be

P.68

important in ensuring that cloned DNA would not somehow escape and infect or contaminate other cells and perhaps even multinucleated organisms. This issue was of major concern at the onset of this research.

Figure 3-19 Principles of DNA cloning using the plasmid pBR322, which has two antibiotic-resistant sites to the drugs ampicillin (A) and tetracycline (T). If only one of these two sites is used for insertion of DNA fragments (in this example, site A), the growth of the carrier bacterium can still be controlled by tetracycline. The figure does not show the restriction enzymes used in cutting the DNA.

Figure 3-20 Model of a DNA construct in which promoter and enhancer sequences from another source were incorporated into the plasmid. Any nucleotide sequence, either derived from an actual DNA or synthesized in vitro, can be inserted. In this manner, almost any gene or portion of a gene can be replicated and studied.

Many different plasmids are now in use. They can be selected for specific purposes and their nucleotide sequences can be matched with the sequences of the DNA fragments to be inserted. The use of this technique and its variants, notably the use of the so-called **cosmids**, combining some sequences of phages with plasmids, created a system in which **any fragment of DNA could be grown in bacteria in a test tube**. With the passage of time, techniques became available for constructing artificial sticky ends of DNA segments, thereby enlarging still further the options of this technology. To ensure replication, such fragments can also be provided with promoter or enhancer sequences taken from another, irrelevant fragment of DNA—for example, of viral origin. Constructs composed of various fragments of DNA or cDNA can be made and inserted into plasmids or vectors (Fig. 3-20). If one considers that **fragments of DNA may represent specific genes**, responsible for the synthesis of important proteins, the mechanism was in place for in vitro **production of useful products** such as hormones. Other applications of this technology include specific sequences of DNA, which may now be isolated or synthesized and reproduced in vitro, to serve as **probes for testing for the presence of unknown genes** or infectious agents, such as viruses.

METHODS OF GENE ANALYSIS AND IDENTIFICATION

Southern Blotting

The analysis of genes can be carried out by a blotting technique devised in 1975 by E. M. Southern. The technique is based on the principle of DNA replication, described above, specifically the immutable and constant association of purine and pyrimidine bases (G-C and A-T), and the constant direction of replication or transcription from the 5' to 3' end. The assumption of the technique is that two fragments of DNA will unite (anneal, hybridize), if they have complementary nucleotide sequences.

To perform the examination, **fragments of DNA**, obtained by means of one or more restriction enzymes, **are separated by electrophoresis** in the loosely structured gel of the sugar,

agarose. The fragments, which travel in the gel according to size (the smaller the fragment, the farther it will move), are then treated with an alkaline solution or by heating, which breaks the bonds between the two chains of the double-stranded DNA. The gels, with the DNA fragments, are then treated with an appropriate buffer solution, and the **DNA is transferred** by capillary action to a matching sheet of nitrocellulose paper (or another suitable solid support material). The fragments of DNA on the nitrocellulose paper, representing an exact replica of the fragments separated in agarose gel, can be processed in several different ways. They can be **removed for sequencing** or gene amplification technique (see below), **or** they can be **annealed (matched) with “probes”** to determine whether the unknown DNA contains normal or abnormal genes or fragments of genes of known identity. The probes can be a DNA fragment of known composition, purified mRNA, or cDNA that is **labeled**, by a process known as **nick translation**, with a radioactive compound such as phosphorus (P^{32}). The bands can also be visualized by labeling the DNA probe with a fluorescent compound, such as ethidium bromide. Most DNA probes used today are fairly short specific sequences of DNA, rarely numbering more than several hundred nucleotides. After washing in a suitable solution to remove surplus probe and to ensure appropriate conditions of correct matching of the probe with the target DNA, the nitrocellulose paper is placed on top of a photographic plate, which must be developed in a darkroom for several days until the radioactivity of the label produces a signal on the photographic emulsion. After developing, the plate will reveal the **position of the fragments of DNA matching the probe** (Fig. 3-21). The fragment can be assessed in several ways: its size can be determined by comparison with a control probe of known size (usually expressed in thousands of nucleotide bases; kb). The expression of a gene can be studied according to the **size of the radioactive band** when compared with controls: a broader band will usually signify a higher activity of the gene, a narrower band indicates a reduced activity. Gene abnormalities can be detected by slight differences in the position of a gene on the blot. These comparisons are usually carried out by presenting the findings side by side as a **series of lanes**, each lane corresponding to one analysis (Fig. 3-22).

Southern blotting can be carried out under **stringent** and **nonstringent conditions**, defined by the experimental setting, such as salinity, temperature, and the size of the DNA probe. Under **stringent conditions**, the annealing of the nucleotides (hybridization) will take place only if the test molecule and the probe have **precisely matching nucleotide sequences**. Under **nonstringent conditions**, the annealing of the fragments may occur when the **nucleotide sequences are approximate**, and precise matching of fragments is not necessary. To give an example from an area of importance in diagnostic cytology, the presence of **human papillomaviruses (HPV)**, in general, may be determined by hybridization of cellular DNA with a cocktail of probes

P.69

under nonstringent conditions. Under these circumstances, all HPVs have a sufficient number of similar nucleotide sequences to attach to the unknown DNA. If, however, the search is for a specific viral type, the hybridization must be performed under stringent conditions (see Chap. 11).

Figure 3-21 Principles of Southern blotting (developed by E.M. Southern, 1975). Kb indicates kilobases, the size of DNA fragments in a blot.

Dot (Spot) Hybridization

Dot hybridization is a variant of the Southern technique in which the target DNA is not treated with endonucleases but **placed in minute amounts (spotted) onto a filter membrane** and denatured by heat or treatment with alkali. The probe is labeled as described above, hybridized to the filter, and an autoradiograph is obtained. The procedure, requiring only minute amounts of target DNA, may serve as a screening test against several labeled probes. This technique and its variants have been adopted to the **DNA and RNA microarrays** that allow the recognition of known genetic sequences in unknown DNA or RNA.

Figure 3-22 Southern blot of a human papillomavirus type 18, carried in the plasmid pBR322. *Left.* Sites of activity of several restriction enzymes (*EcoR*I, *Hind*III, *Bam*HI) and the size of DNA fragments in kilobases (Kb). *Right.* Southern blot in which the DNA fragments were separated according to size (indicated on the right). The “lanes” are numbered on top to compare the sizes of fragments in several experiments.

In Situ Hybridization With DNA Probes

The technique of in situ hybridization is based on principles similar to Southern blotting. Instead of hybridizing fragments of DNA on a piece of nitrocellulose paper, **the target of in situ hybridization is naturally occurring DNA, which may be present in the nucleus of a cell or on a chromosome.** The purpose of in situ hybridization is to identify the presence of a gene or another DNA sequence (such as a DNA virus) and to identify its location within the target. The procedure shares some of the basic principles with Southern blotting: The target DNA, such as nuclei in a tissue section, a smear, or a chromosomal preparation, must be denatured to separate the two strands. This is usually done by heating or by treatment with hydrochloric acid or alkali. The nick-translation **labeled DNA probe** is then applied under stringent or nonstringent conditions (Fig. 3-23). The label may be a **radioactive compound** (such as radioactive phosphorus, sulfur, or tritiated thymidine) that requires the use of a photographic emulsion to document

P.70

a positive reaction, after a lengthy period of incubation. The probe may also be labeled with a **biotin-avidin complex** that allows the demonstration of the results by a peroxidase-antiperoxidase reaction visible under a light microscope. The latter procedure is much faster but less sensitive than the radioactive label. The results of in situ hybridization of a cervical biopsy with DNA from HPV types 11 and 16 are shown in Chapter 11. **Hybridization of entire chromosomes or their segments**, to determine the location of a particular gene, is based on essentially the same principles. The technique of **fluorescent in situ hybridization (FISH)** is particularly valuable in this regard. Using probes labeled with fluorescent compounds, the **location of chromosomes** in the interphase human nucleus (see Fig. 2-31 and Chap. 4), the **number of chromosomes in a nucleus**, the **presence of specific genes or gene products** could be identified. By the use of specific probes, the abnormalities of chromosomes in several forms of human cancer could be defined and documented (see Chap. 4).

occur when the nucleotide sequences of the native DNA and of the probe match.

In Situ Hybridization With mRNA

mRNA may also be used in a hybridization system *in situ*. The **mRNA probes** may be developed from known DNA sequences of genes or segments of genes, or they may be synthesized according to a sequence of amino acids in a protein molecule. Such mRNA probes will **hybridize with corresponding sequences of DNA or cDNA**. By using the ingenious techniques of molecular engineering, it is also possible to construct “**antisense**” probes that will hybridize with mRNA and thus **reveal the presence of actively transcribing genes in situ**. Such probes have been used by Stoler and Broker to detect mRNA of HPV in tissue sections from the uterine cervix (see Chap. 11).

Restriction Fragment Length Polymorphism

Restriction fragment length polymorphism (RFLP) is another form of gene analysis by Southern blotting, which is carried out by comparing the effects of selected restriction endonucleases on unknown DNA. **The addition or subtraction of a single nucleotide in the DNA sequence may alter significantly the recognition sites for the endonucleases**. Therefore, a comparison of the size and position of the DNA fragments on the blot may reveal similarities or differences between the DNAs from two individuals. It has been documented that each person has **unique DNA sequences that are akin to genetic fingerprints**, based mainly on the structure of noncoding DNA (see above). The RFLP technique has found application in human genetics, in the study of cancer, and in forensic investigations. A somewhat similar technique is based on the individual variations in **short tandem repeats** in noncoding DNA and is known as **variable number tandem repeats**, which is used for purposes similar to those for the RFLP technique.

Northern Blotting

Northern blotting (so named to differentiate it from Southern blotting, but not named after a person) is based on **techniques of isolation of RNA** from rapidly frozen cells or tissues. Among the RNAs, a small proportion (about 2%) represents mRNA that can be identified and separated by virtue of its poly-A tail (see above). The RNA of interest is separated by size, using **agarose gel electrophoresis** (with a denaturing solution, such as formamide, added), and transferred to a stable medium, such as nitrocellulose paper, by techniques similar to those used in Southern blotting. The subsequent hybridization procedure is carried out with appropriate probes, which may consist of DNA or cDNA. **The identification of the appropriate mRNA molecule indicates that a gene (or a DNA sequence) is not only present but has also been actively transcribed**, information that cannot be obtained by Southern blot analysis. The issue is of importance in the presence of several similar or related genes, as it allows the identification of a gene that is active under defined circumstances.

Western Blotting

Western blotting is a technique similar to Southern and northern blotting, except that the matching involves proteins

rather than DNA or RNA, and the **probe is an antibody to a given protein**. The technique

has been particularly useful in determining whether an antibody produced in an experimental system matches the amino acid sequence of an antigen and as an important step in **quantitation of gene products** by means of an antigen-antibody reaction. The technique may also be used to determine whether a protein produced in vitro matches a naturally occurring protein. The technique is important in verifying the purity of synthetic genes and gene products. As an example, a hormone produced in vitro may be matched with a hormone extracted from an appropriate tissue. See above comments on proteomics.

Polymerase Chain Reaction

In 1985, Saiki and associates described a new ingenious method of **DNA amplification**—now known as **polymerase chain reaction or PCR**.

The principle of the technique is the observation that if the synthesis by **DNA polymerase** of a segment of double-stranded DNA is initiated at both ends of the two complementary chains, the replication will continue until the entire molecule is reproduced. In order to initiate this synthesis, three conditions have to be met:

1. The **two chains of the target DNA molecule** must be separated by **heating**.
2. The **complementary two fragments of DNA or primers**, corresponding to known sequences of nucleotides at the two ends of the target molecule, also known as **flanking sequences**, must be synthesized. Thus, the exact sequence of nucleotides of the target molecule has to be known in advance.
3. DNA polymerase capable of functioning at high temperatures (**heat-stable polymerase**) must be identified.

The most commonly used, **Taq polymerase**, was derived from a bacterium, *Thermus aquaticus*, living in a hot geyser in Yellowstone National Park. The concept was proposed by an employee of a then-fledgling biotechnology company, the Cetus Corporation. The employee, Kary B. Mullis, received a Nobel Prize for his contribution (Rabinow, 1995).

The principle of the method is as follows: a target segment of double-stranded DNA is heated to separate the complementary strands. Two short sequences of **synthetic DNA**, known as **primers**, each corresponding to a specific flanking nucleotide sequence of the target DNA **are mixed with the target DNA**. The primers mark the beginning and the end of the synthesis. The primers bind (**anneal**) to the flanking sequence of the target DNA, based on the fundamental principles of DNA replication. In the presence of a “soup” containing a mixture of the four essential nucleotides (A,C,G,T), the **heat-stable polymerase** copies the sequence of nucleotides in each strand of the target DNA (a function known as **primer extension**), creating two double-stranded DNA sequences. The mixture is then cooled to facilitate **reannealing** of the complementary DNA strands. In the second cycle, the two copies of the newly created double-stranded DNA are again separated (**denatured**) by heat, thus creating four copies. Using the same primers and the same procedure, the four copies will become eight. The procedure may be repeated over several cycles of amplification. Each cycle consists of primer extension, denaturation, and reannealing, conducted under various conditions of time and temperature. After 20 cycles, the number of copies of the original target DNA fragment will grow to over 1 million (exactly 1,048,576 copies). The results are tested by Southern blotting techniques for the presence of the now-amplified segment of DNA, which may be a gene or a part thereof. The technique may reveal the presence of a single copy of a small gene, such as an infectious virus, that would not be detectable by any other technique (Fig. 3-24).

The PCR technique and its variants has found many applications in various aspects of basic and forensic and even agricultural sciences. The technique can be applied to individual **cells in situ** and to the identification of DNA viruses and of bacteria. The ability to amplify minuscule amounts of DNA will continue to find an ever-increasing applicability in various fields, particularly with introduction of new thermostable polymerases, improved machines, known as **thermal cyclers**, and full automation of the process.

Denaturing Gradient Gel Electrophoresis

A clever way of discovering mutations in genes is the technique of **denaturing gradient gel electrophoresis (DGGE)**. The concept of this technique is based on **differences in melting point (separation) of DNA double-stranded chains** in acrylamide gels mixed with a denaturing solution of urea and formamide. A gradient of the denaturing solution is created in an acrylamide gel, and the **gene product** obtained by polymerase chain reaction (PCR) is **electrophoresed** in the gel for about 8 hours. The gel is stained with ethidium bromide, which binds to DNA, and the bands are visualized under ultraviolet light. **DGGE separates DNA fragments based on nucleotide sequence rather than size**. Differences as small as a single nucleotide change will result in bands in a different position on the gel.

Monoclonal and Polyclonal Antibodies

The subject of monoclonal and polyclonal antibodies and their role in immunochemistry in tissues and cells is considered in detail in Chapter 45. Because the techniques were developed as a consequence of progress in molecular biology and because they are particularly useful in diagnostic histopathology and cytopathology, they will be briefly described here.

In 1975, Kohler and Milstein observed that splenic **B lymphocytes of mice, programmed to produce a specific antibody by injection of an antigen, could be fused with cultured plasma cells**. Plasma cells are, in essence, living factories for the production of immunoglobulins. As a consequence

P.72

of the fusion, they produced the specific immunoglobulin or antibody expressed in the B lymphocytes. It is now possible to generate antibodies of varying degrees of specificity to almost any protein. As an example, highly specific antibodies to various species of intermediate filaments can be produced and used to localize and identify the presence of such filaments by immunohistologic and immunocytologic techniques. Another example is the production of antibodies to cell surface antigens (CDs) and various oncogene products that are important in classification of lymphomas and leukemias. Specific cell products, such as hormones, may also be identified by this technique.

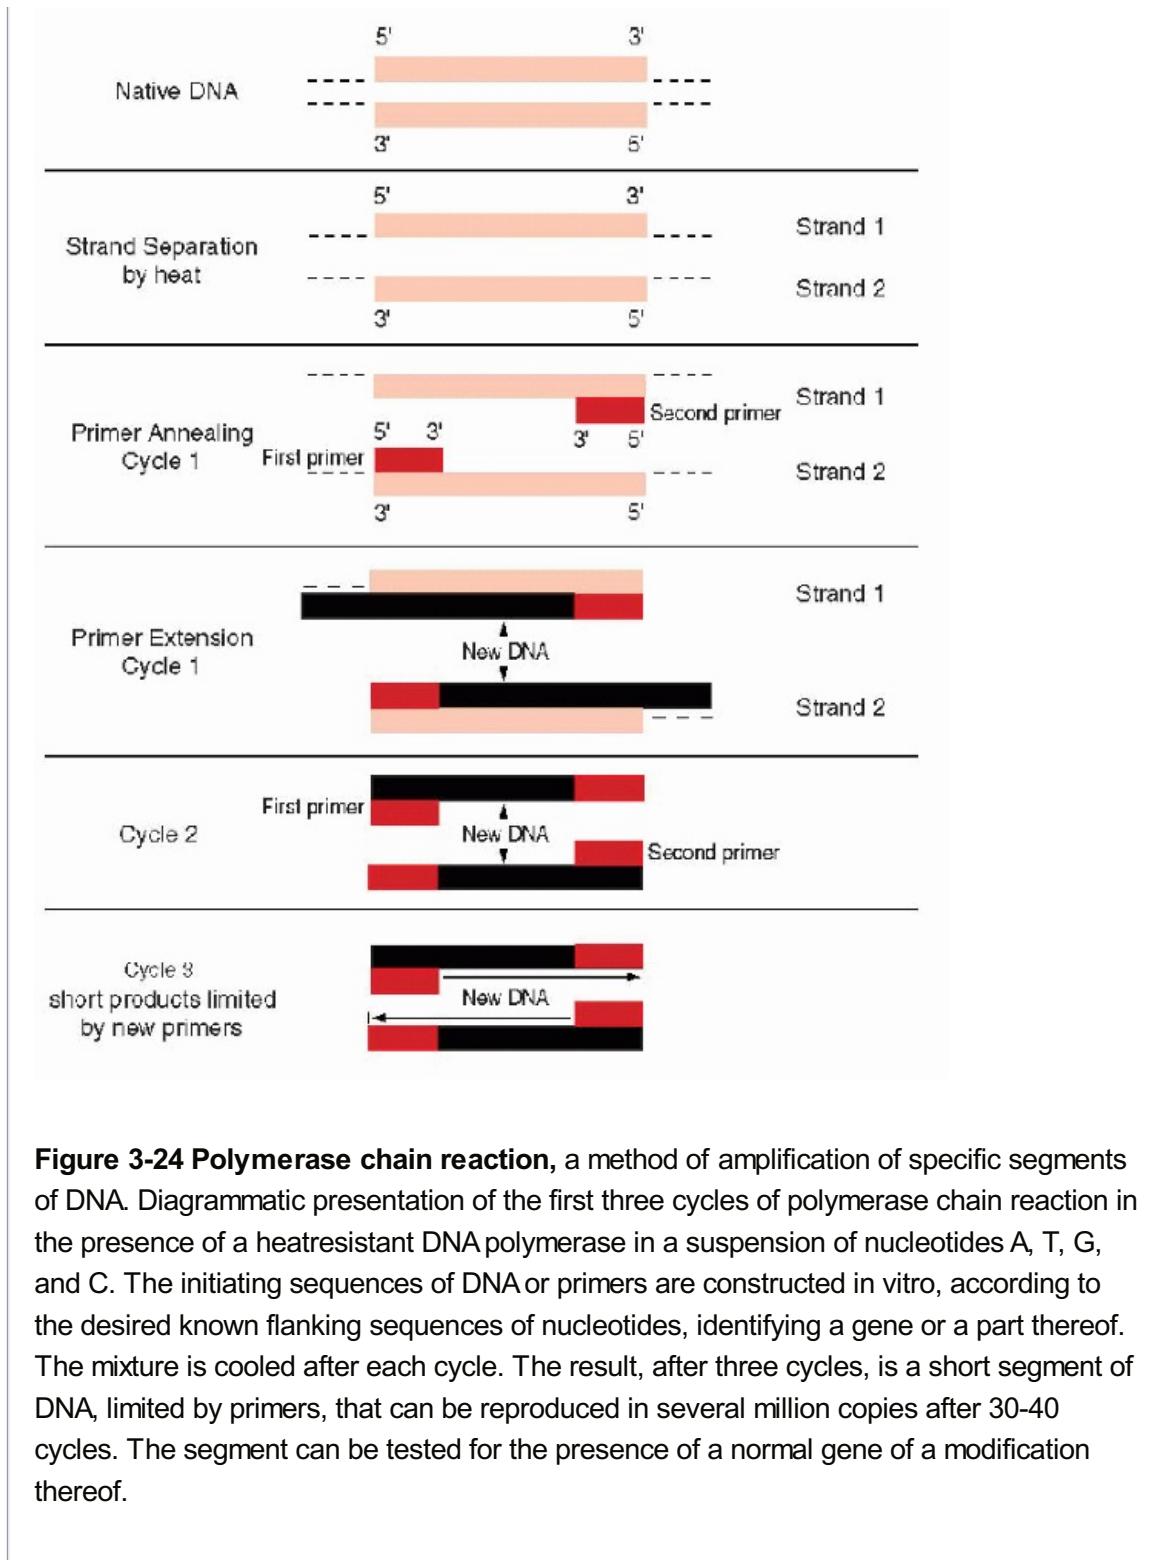

Figure 3-24 Polymerase chain reaction, a method of amplification of specific segments of DNA. Diagrammatic presentation of the first three cycles of polymerase chain reaction in the presence of a heatresistant DNA polymerase in a suspension of nucleotides A, T, G, and C. The initiating sequences of DNA or primers are constructed in vitro, according to the desired known flanking sequences of nucleotides, identifying a gene or a part thereof. The mixture is cooled after each cycle. The result, after three cycles, is a short segment of DNA, limited by primers, that can be reproduced in several million copies after 30-40 cycles. The segment can be tested for the presence of a normal gene or a modification thereof.

APPLICABILITY OF MOLECULAR BIOLOGY TECHNIQUES TO DIAGNOSTIC CYTOLOGY

Several of the developments discussed in the preceding pages proved to be of direct or indirect value in diagnostic cytology. Molecular biologic techniques can be applied to the **identification of many infectious agents**, such as bacteria, fungi, and viruses. Of special significance in diagnostic cytology has been the characterization of **HPV** that may play a role in the genesis of cancer of the uterine cervix, vagina, vulva, and the esophagus, discussed in appropriate chapters. The techniques of **in situ hybridization** have been applied in a number of diagnostic

situations, for example, in the determination of the presence of various types of HPV in precancerous lesions and cancer of the various organs wherein this virus may be carcinogenic. The molecular techniques have also shed some light on the events in human cancer, which are discussed in Chapter 7. In this regard, in situ hybridization techniques with probes to chromosomes or chromosomal segments have been shown to be of value in documenting chromosomal and genetic abnormalities useful in the diagnosis and prognosis of cancer cells in various situations, discussed in appropriate chapters. **Southern blotting techniques** have been applied, among others, to the study of apoptosis, an important phenomenon in diagnostic cytology (see Chap. 5). There are also several diagnostic applications of Southern blotting, for example, to the diagnosis of malignant lymphoma and nasopharyngeal carcinoma in aspirated samples of lymph nodes (Lubinski et al, 1988; Feinmesser et al, 1992). **In situ amplification techniques**, applicable to cytologic preparations, were discussed by O'Leary et al (1997). The presence of various oncogenes and tumor suppressor genes can be documented and quantitated by **immunocytologic techniques**, and some of these approaches have been shown to be of prognostic significance (for example, in breast cancer, see Chap. 29). **Proteomic evaluation**, previously applied to tissues

P.73

(Liotta et al, 2001; Paweletz et al, 2001) can also be applied to archival cytologic material (Fetsch et al, 2002).

Other techniques that may be applicable to cytologic samples are **microarrays** and **comparative genomic hybridization**. As briefly mentioned above, the **DNA microarray technology** is the consequence of the human genome project and is based on principles of in situ hybridization. **DNA of unknown samples** is hybridized **against a large array of known genes**, placed on a slide or a plate. The matching genes may be identified by a color reaction and the collection and analysis of observations requires a computer analysis (recent reviews include Golub et al, 1999; Khan et al, 2001; Welsh et al, 2001). King and Sinha (2001) described at length the promise and pitfalls of this technology. Macoska (2002) discussed the utility of DNA microarrays as a tool in prognosis of human cancer (see also Chap. 4).

Comparative genomic hybridization compares the unknown DNA against a metaphase karyotype of known cells. Excess or loss of chromosomes or their segments is analyzed in a computerized microscope (Kallioniemi et al, 1992; Maoir et al, 1993; Houldsworth and Chaganti, 1994; Wells et al, 1999; Baloglu et al, 2001) (see also Chap. 4).

Immunocytochemistry is discussed in Chapter 45.

THOUGHTS FOR THE FUTURE

The question of whether molecular biology will soon provide answers to the question, "How cells function?" is difficult to answer at this time. It is evident that the fundamental questions pertaining to the role of DNA, RNA, and proteins in cell function and heredity have been answered to some degree within the last 50 years. There remain, however, many questions of mechanisms of the interplay and the relationship among an ever-growing number of genes and proteins that somehow manage to keep the healthy cell working as a harmonious whole. A special puzzle of interest to the readers of this book is the sequence of events in cancer, discussed in Chapter 7. For many reasons, the issue is complicated because many of the genes implicated in cancer also participate in the life events of normal cells, such as DNA replication and cell cycle regulation. Some years ago, I compared the present status of molecular biology research to a swarm of woodpeckers, each attempting to identify a worm (by

analogy, a protein). It would be difficult, if not impossible, to attempt to understand how the tree grows by a synthesis of the knowledge gained by the entire swarm of woodpeckers (Koss, 1989).

The great chemist, Erwin Chargaff, who contributed significantly to Watson and Crick's discovery of DNA structure, had this to say in an article in *Science* published in 1971:

"In the study of biology, the several disciplines exist next to each other, but they do not come together. We have no real idea of the inside of a living cell, for we lack what could be called a science of compressed spaces; we lack a scientific knowledge of a whole; and while a sum can be subdivided, this is not true of a whole. I know full well, science progresses from the simple to the complex. I, too, have been taught that one must begin at the bottom; but shall we ever emerge at the top?"

Appendix

GLOSSARY OF TERMS COMMONLY USED IN MOLECULAR BIOLOGY

AAAA ...:

sequence of adenine molecules terminating the chain of mRNA (poly-A tail)

allele:

an alternative form of a gene

alternative splicing:

a regulatory mechanism by which variations in the incorporation of a gene's exons, or coding regions, into mRNA lead to the production of more than one related protein, or isoform

amplification:

enhancement of a gene(s), usually using a specific enzyme

annealing:

fusion of two matching molecules (chains) of DNA or DNA with mRNA

anticodon:

a sequence of nucleotides in transfer RNA (tRNA), corresponding to a codon sequence for one specific amino acid, inscribed on mRNA; a mechanism used in translation of mRNA messages into proteins

antioncogene(s):

genes believed to counteract the effect of oncogenes (see Rb gene and p53)

antisense:

a strand of DNA that has the same nucleotide sequence as mRNA; a strand of mRNA that has the same nucleotide sequence as DNA

AUG (adenine, uracil, guanine):

a base sequence (codon) on mRNA signaling the amino acid methionine, which initiates the synthesis of a protein

BamI:

widely used restriction enzyme (endonuclease), derived from *Bacillus amyloliquefaciens* (see restriction endonuclease)

base pairs:

matching pairs of nucleotides, such as adenine (adenine-thymine or guanine-cytosine) in the two matching strands of the DNA molecule

bases:

colloquial designation of pyridine and pyrimidine bases (nucleotides) that enter into the makeup of nucleic acids (see base pairs)

box:

a sequence of nucleotides of known constant composition serving as a signal for the beginning of a transcriptional event or the end of it

capsid:

protein coat of viral particles

chromosome walking:

a technique that allows a rapid search for gene identification and location on a chromosome

codon:

a sequence of three nucleotides encoding one amino acid; the code is usually expressed in RNA nucleotide sequences (see AUG)

construct:

a DNA or RNA vector, such as a plasmid or a virus, engineered to express a nucleotide sequence. The constructs are often provided with promoters and enhancers borrowed from other cells or viruses

P.74

cDNA (complementary DNA):

a molecule of DNA complementary to RNA, usually generated by means of the enzyme reverse transcriptase

cut (DNA):

synchronous breaking (cutting) of both chains of a double-stranded molecule of DNA, usually accomplished with the help of one of the enzymes known as *restriction enzymes* or *endonucleases*. The cut may result in smooth ends or uneven (sticky) ends of the DNA chain. If a single strand of DNA is affected, the term "nick" is used (see nick translation)

denaturing gradient gel electrophoresis (DGGE):

a method of discovering genetic changes based on differences in DNA melting (separation of double-stranded DNA into single chains) caused by substitution of one or more bases

dot blot:

analysis of several small samples of DNA of unknown makeup to identify the presence of a known DNA or mRNA sequence, such as the presence of a virus

downstream:

an event happening before the main biologic event. For example, a signal encoded in the DNA that has to be recognized by the appropriate enzyme before transcription into mRNA can take place. The concept is based on the constant direction of all transcriptional events in nucleic acids from the 5' end of the sugar molecule to the 3'. A **downstream event, therefore**, must happen in the direction of the 3' end of the molecule. The exact opposite is true of an "upstream" event

EcoRI:

a widely used restriction enzyme (endonuclease), derived from *Escherichia coli* (see restriction endonuclease)

enhancers:

DNA sequences known to promote transcription

episome (episomal):

a circular gene or gene fragment, not integrated into host DNA

exon:

the sequence of nucleotides in a gene corresponding to a final product (e.g., a protein [Cfr. intron]) a region of a gene that codes for a protein

five prime (5'):

pertains to carbon location in the molecule of sugar (ribose, deoxyribose) in the chain of nucleic acids. The synthesis of nucleic acids (and their products) always proceeds in the direction of 5' to 3', the 3' indicating the location of carbon in the sugar molecule to which the next molecule of phosphate attaches itself

frame-shift mutation:

the addition or deletion of a number of DNA bases that is not a multiple of three, thus causing a shift in the reading frame of the gene. This shift leads to a change in the reading frame of all parts of the gene that are downstream from the mutation, often leading to a premature stop codon and, ultimately, to a truncated protein

gene:

a segment of DNA (or corresponding RNA) encoding one protein; each gene is composed of exons and introns

gene library:

a collection of genes, usually corresponding to one species, such as human

genetic engineering:

methods of gene replacement, substitution or propagation in vitro, serving to produce molecules of biologic value, such as hormones, to treat genetic diseases, or to modify plant or animal species

genome:

a collection of genes representing the entire endowment of an organism, also reflected in a single normal cell (other than a gamete). Not all of the genes inscribed in the DNA will be active at any given time

genomics:

the study of the functions and interactions of all the genes in the genome, including their interactions with environmental factors

heteroduplex:

double-stranded DNA wherein the two strands are of different origin, such as two individuals of the same species, or two related, but not identical, DNA viruses. Such strands often show differences in nucleotide sequences that will prevent their perfect match. The matching or absence thereof can be visualized under the electron microscope under stringent and nonstringent conditions. The method is used to document similarities and differences between

and among DNA sequences, for example, in typing of DNA viruses, such as the HPV

heterozygous:

having two different alleles at a specific autosomal (or X chromosome in a female) gene locus

homozygous:

having two identical alleles at a specific autosomal (or X chromosome in a female) gene locus

initiation codon:

the sequence of nucleotides indicating the beginning of protein synthesis, usually AUG coding for methionine

intron:

(intervening sequence): a part of the gene inscribed in DNA that is transcribed into mRNA, but is excised before the final molecule of mRNA is produced by splicing of exons

jumping genes:

transposable segments of DNA accounting for adaptation of some species to environmental conditions

lac (operon):

a sequence of genes in *E. coli*, regulating the metabolism of the sugar lactose

ligase:

an enzyme binding together fragments of DNA

linker:

a segment of DNA (usually synthetic), that contains a nucleotide sequence corresponding to a restriction enzyme; used in gene splicing (binding) and in genetic engineering

melting (DNA):

separation of the two chains of double-stranded DNA molecule by heat, acid, alkali, or a denaturing solution (urea and formamide)

missense mutation:

substitution of a single DNA base that results in a codon that specifies an alternative amino acid

motif:

a DNA-sequence pattern within a gene that, because of its similarity to sequences in other known genes, suggests a possible function of the gene, its protein product, or both

P.75

mRNA:

messenger RNA, a link between the DNA and the production of proteins. mRNA is transcribed off DNA and translated into a protein molecule

mutation:

a spontaneous or artificial change in sequence of nucleotides, resulting in a modified protein product

myc (c-myc):

an oncogene located in the nucleus of cells

nick:

a cut of one of the two chains of DNA. This technique is useful in incorporation of one type of

DNA into another

nick translation:

a technique for labeling DNA with radioactive or optical probes, such as biotin, useful in in situ hybridization and similar analytical procedures

nonsense:

a genetic message that does not correspond to a viable or useful product (e.g., a protein) that is often destroyed

nonsense mutation:

substitution of a single DNA base that results in a stop codon, thus leading to the truncation of a protein

northern blotting (analysis):

analysis of unknown RNA performed by electrophoretic isolation of RNA sequences and subsequent match with a molecule (gene) of RNA or DNA of known composition

oncogene(s):

growth-promoting genes, initially identified in rodent cells and found to be essential in malignant transformation of these cells by RNA viruses. Many similar genes have since been identified in virtually all multicellular organisms, including humans (see protooncogenes and *myc* and *ras*, as examples of oncogenes)

operator:

a region of DNA that regulates the use of a metabolite (e.g., a sugar), working in tandem with a repressor gene

operon:

a metabolic function of the cell, usually associated with repressor and operator genes

p21:

protein product of *ras* oncogene; another p21 is a protein associated with p53

palindrome:

a self-complementary nucleotide sequence, often recognized by restriction enzymes

phage:

a bacterial virus, the target of some of the initial studies on DNA, still very useful in molecular engineering

p53:

a gene known as “guardian of the genome,” essential in prevention of DNA transcription errors and often mutated in various forms of human cancer

plasmid:

a self-replicating fragment of circular, double-stranded DNA, living in bacteria and sometimes conferring upon the host organism the ability to resist antibiotics. Extensively used in various forms of molecular manipulation and engineering

point mutation:

the substitution of a single DNA base in the normal DNA sequence

polyadenylation:

sequence of adenyl molecules (see AAAAA...)

polymerase:

enzymes that mediate the assembly of DNA or RNA fragments into a cohesive larger unit

polymerase chain reaction (PCR):

a technique of DNA amplification, based on the use of initiation sequences of a gene (a primer) and a thermostable DNA polymerase. The technique can be used to reproduce innumerable copies of a single DNA segment or a gene

promoter:

a sequence of DNA nucleotides signaling the attachment of RNA polymerase as an initiation point of mRNA transcription; such sequences are extensively used in molecular engineering

protooncogene:

widely disseminated growth-regulating genes; when overexpressed or modified (mutated), these genes become oncogenes

***ras*:**

an oncogene commonly found in many malignant human tumors

Rb gene (retinoblastoma gene):

a regulatory gene first identified in patients with the rare malignant tumor of the retina. Its congenital absence leads to the development of the tumor; hence, this is the prime example of an antioncogene

regulatory gene:

genes regulating the function of other genes, such as a repressor gene

restriction endonuclease:

enzymes of bacterial origin that cut nucleic acids at the site of a predetermined nucleotide sequence (see examples under Bam1 and EcoRI)

restriction enzyme:

colloquial for restriction endonuclease restriction fragment length

restriction fragment length polymorphism (RFLP):

a technique of comparison of DNA fragments obtained by restriction enzymes, very useful in identification of individuals and extensively used in comparative genetics and forensic work

reverse transcriptase:

an enzyme capable of translating a message inscribed in RNA into the corresponding DNA, known as complementary DNA (cDNA)

RNA splicing:

attachment of exons to each other, after excision of introns, to form a final molecule of mRNA. The term is also used in other forms of gene manipulation

rRNA:

ribosomal RNA, mainly produced in the nucleolus and a component part of ribosomes, cytoplasmic organelles, essential in the formation of proteins

single-nucleotide polymorphism (SNP):

a common variant in the genome sequence; the human genome contains about 10 million SNPs

Southern blotting:

a method of DNA analysis first described by Southern (1975), in which unknown DNA is cut into

fragments. The fragments are isolated by electrophoresis, transferred to a suitable paper, and matched for the presence of known genes with labeled probes that are usually DNA, but can also be RNA

start codon:

see initiation codon

sticky ends:

double-stranded DNA in which one chain is longer than the other, often the result of cutting with a restriction enzyme. This technique is very useful in combining two disparate molecules of DNA

stop codon:

a codon that leads to the termination of a protein rather than to the addition of an amino acid. The three stop codons are TGA, TAA, and TAG

suppressor gene:

a gene that prevents another gene's expression

P.76

template:

a term used to define a nucleotide sequence in DNA, to be transcribed into RNA

tRNA:

transfer RNA, essential in synthesis of proteins (see anticodon)

transcription:

formation of RNA from a DNA

transduction:

transfer of genetic material from one cell to another by means of a vector, such as a virus

transfection:

transfer (infection) of DNA or RNA from one cell to another by means of a vector

translation:

the mechanism of protein formation from messages inscribed in RNA

vector:

an agent, such as a plasmid or a virus, capable of multiplication in bacteria or other living cells, that can be used to transfer genetic information encoded in DNA or RNA

western blotting:

matching of protein molecules, one of known composition and the other unknown. The method is extensively used in testing the specificity of immunologic reagents (such as antibodies) with an antigen of known makeup

Principles of Cytogenetics*

Linda A. Cannizzaro

The events governing the developmental evolution of cells as they progress from the fertilized ovum to mature tissues are not fully understood as yet. It is known, however, that this process involves extensive **proliferation and differentiation of embryonal stem cells** and their **selective destruction** by programmed cell death or **apoptosis** (see Chap. 6). These processes are governed by messages inscribed in the nuclear deoxyribose nucleic acid (DNA) (see Chap. 3). The key feature in cell proliferation is **cell division**.

There are two forms of cell division, one occurring during the formation of **gametes** (e.g., the spermatozoa and ova), known as **meiosis**, and the other affecting all other cells (**somatic cells**) known as **mitosis**. The **purpose of meiosis** is to **reduce the number of chromosomes by one half** (in humans from 46 to 23) in the gametes, so that the union of a spermatozoon and an ovum (fertilization of the ovum) will result in an organism that carries the full complement of chromosomes (in humans, 46) in its somatic cells. The **purpose of mitosis** is the reproduction of somatic cells, each carrying the full complement of chromosomes. Both forms of cell division are discussed in this chapter.

P.80

The events encompassing the life of a cell from its birth until the end of the mitotic division are known as **the cell cycle**, during which the **genomic identity** of the cell, vested in the **DNA**, must be preserved. Molecular genetic technology has considerably advanced our knowledge of the processes involved in the progression of the cell cycle. The normal cell cycle has developed complex mechanisms for the detection and repair of damaged DNA. Upsetting the intricate balance of these cellular processes has dramatic and usually tragic consequences.

Dysregulation of meiosis oftentimes is manifested as a **genetic disorder**, while **dysregulation of mitosis** may result in a **malignant disorder**.

Since the demonstration of the specificity of chromosomal changes in many disease states and their utilization in diagnosis, the cytogenetic aspects of human diseases have become of direct concern to the practicing physician. This chapter summarizes the salient features of cell division, as well as some of the inherited and malignant conditions that directly result from faulty or anomalous events during meiosis and mitosis. Recent introduction of several powerful molecular cytogenetic methods has facilitated the identification of chromosomal alterations previously irresolvable by high-resolution cytogenetic analysis. These technologies, including the recent mapping of the human genome (Caron et al, 2001; International Human Genome Sequencing Consortium, 2001; Venter et al, 2001; Peltonen and McKusick, 2001) have enormously impacted our knowledge of human genetic disease and the contributions made by these innovations will be made evident in the forthcoming narrative.

THE CELL CYCLE

The cell cycle is composed of several phases, which have, for their purpose, the preservation of the genomic heritage of the cell to be transmitted to the two daughter cells.

The phases of the cell cycle are as follows:

- G₀ (resting phase)
- G₁ (gap¹)
- S (synthesis)
- G₂ (gap²)
- M (mitosis)

The events in the phases of cell cycle are described below.

Events Preparatory to Cell Division

Genetic information in the form of DNA is stored within the interphase nucleus in thread-like, tangled structures called **chromatin**. During the process of cell division, the DNA condenses and divides into several distinct pairs of linear segments or **chromosomes**. Each time the cell divides, the hereditary information carried in the chromosomes is passed on to the two newly formed cells. The DNA in the nucleus contains the instructions for regulating the amount and types of proteins made by the cell. These instructions are copied, or transcribed, into messenger RNA (mRNA), which is transported from the nucleus to the ribosomes located in the cytoplasm, where proteins are assembled (see Chap. 3).

Most somatic cells spend the greater part of their lives in G₀, or the resting phase of the cell cycle, because such cell populations are not actively dividing.

Before a cell can divide, it must double its mass and duplicate all of its contents. This ensures the ability of the daughter cells to begin their own cycle of growth followed by division. Most of the work involved in preparing for division goes on invisibly during the **growth phase of the cell cycle, known as the *interphase***, which comprises the G₁, S, and G₂ phases of the cell cycle (Fig. 4-1). The interphase nucleus is the seat of crucial biochemical activities including the synthesis of proteins and the duplication of its chromosomal DNA in preparation for subsequent cell division.

Cell Division

The **process of cell division** (see Fig. 4-1) can be readily visualized in the microscope and consists of two sequential

P.81

events: **nuclear division (mitosis)** followed by **cytoplasmic division (cytokinesis)**. The cell-division phase is designated as the *M phase* (**M = mitosis**). The period between the end of the M phase and the start of DNA synthesis is the *G₁ phase* (**G = gap**). In G₁, RNAs and proteins, including the essential components needed for DNA replication, are synthesized without replication of DNA. Once all the ingredients are synthesized in G₁, DNA replication takes place in the ensuing synthesis phase (**S-phase**) of the cell cycle.

Figure 4-1 Schematic presentation of the phases of the mitotic cycle. After the *M phase*, which consists of nuclear division (mitosis) and cytoplasmic division (cytokinesis), the daughter cells enter the interphase of a new cycle. Interphase begins with the *G₁ phase* in which the cells resume a high rate of biosynthesis after a relatively dormant state during mitosis. The *S phase* starts when DNA synthesis begins and ends when the DNA content of the nucleus has been replicated (doubled); each chromosome now consists of two sister chromatids. The cell then enters the *G₂ phase*, which ends with the start of mitosis (M). The latter begins with mitosis and ends with cytokinesis. During the early part of the M phase, the replicated chromosomes condense from their elongated interphase state and can be seen in the microscope. The nuclear membrane breaks down, and each chromosome undergoes organized movements that result in the separation of its pair of sister chromatids as the nuclear contents are divided. Two nuclear membranes then form, and the cytoplasm divides to generate two daughter cells, each with a single nucleus. This process of cytokinesis ends the M phase and marks the beginning of the interphase of the next cell cycle. Although a 24-hour cycle is shown in this figure, cell cycle times vary considerably in cells, with most of the variability being in the duration of the G₁ phase. (Courtesy of Dr. Avery Sandberg, Scottsdale, AZ.)

The period between the completion of DNA synthesis and the M phase is known as the *G₂ phase*, in which additional cellular components are synthesized in preparation for the cell's entry into mitosis. The interphase thus consists of successive G₁, S, and G₂ phases that normally constitute 90% or more of the total cell cycle time (see Fig. 4-1).

However, following the completion of mitotic division, most normal somatic cells leave the division cycle and enter a **postmitotic resting phase (G₀)**, rather than the new **G₁ phase**. The unknown **trigger mechanism for cell division** is activated during the G₀ phase; as a result, the cell enters G₁ phase and is committed to divide (Brachet, 1985; Levitan, 1987; Therman, 1993; Nicklas, 1997; Hixon and Gualberto, 2000). In fact, experiments have shown that the point of no return, known as the *restriction point (R point)*, occurs late in G₁. After cells have passed this point, they will complete the rest of the cycle at their normal rate, regardless of external conditions. The time spent by cells in G₂ and S phases is relatively constant (Brachet, 1985; Gardner, 2000). One interesting exception is the epidermis of the **skin**, in which **some cells remain in the G₂ phase** and thus are able to undergo rapid division in wound healing.

Studies of the cell cycle in yeast have shown that the **cell proceeds from one phase of the cell cycle to the next by passing through a series of molecular checkpoints** (Li and Murray, 1983). These checkpoints determine whether the cell is ready to enter into the next phase of the cell cycle. These biochemical checkpoints involve the synthesis of new proteins and degradation of already existing proteins. Both the S phase and the M phase are activated by related **protein kinases**, which function at specific stages of the cell cycle. Each kinase consists of at least two subunits, one of which is **cyclin**, so named because of its role in the cell cycle. There are several cyclins involved in regulating entry into different parts of the cell cycle, and they are degraded after serving their purpose or as the cell progresses in the cycle and through mitosis (Rudner and Murray, 1996; Amon, 1999; Cerrutti et al, 2000; Gardner, 2000).

The cells of the human body divide at very different rates. Some cells, such as mature neurons, heart and skeletal muscle, and mature red blood cells, do not divide at all or perhaps only under most exceptional circumstances. Other cells, such as the epithelial cells that line the inside and outside surfaces of the body (e.g., the intestine, lung, and skin), divide continuously and relatively rapidly throughout the life of the individual. The behavior of most cells falls somewhere between these two extremes. Most somatic cells rarely divide, and the duration of their cell cycle may be 100 days or more.

The **average time for the mitotic cycle** in most cell types is about 16 hours in human and other mammalian cells, distributed as follows: S phase, approximately 6 to 8 hours; G₁ phase, 6 to 12 hours; G₂ phase, 4 hours; and M phase, 1 to 2 hours (see Fig. 4-1). The M, and especially G₁, phases may show considerable variation in duration. Most of the available evidence suggests that these periods are **longer in cancer cells** than in benign cells, or at least in benign cell populations that normally have a rapid turnover. Many tissues require more than 16 hours to complete the mitosis (Miles, 1979).

Even though it takes a minimum of 7 to 8 hours for a cell to duplicate its entire chromosomal DNA, individual chromosomes or segments of chromosomes are replicated asynchronously, some of them sooner and faster than others. Thus, some chromosomes, or their segments, will have completed DNA synthesis before others begin. This asynchrony does not follow a simple pattern. The synthesis does not necessarily begin at one point and spread uniformly along the chromosome, but may start at several places on a single chromosome, while others wait their turn for DNA replication. A reproducible phenomenon is the **late replication of one of the two X chromosomes** in normal female cells or in cells with more than one X chromosome.

Apparently, this X chromosome finishes its DNA replication later than any other chromosome in the cell. The number of late-replicating X chromosomes is usually one less than the total number of X chromosomes in the cell (Moore, 1966; Sandberg, 1983a, 1983b).

The chromosomes are not visible under the light **microscope except during the M phase of the cell cycle**. The physical condition of the chromosomes during interphase (e.g., G₁, S, and G₂) is not known, but their invisibility is probably caused, at least in part, to their enormous elongation. The older notion that the chromosomes lose their linear structure and become dissolved in the nucleoplasm is unlikely, and it introduces unnecessary complexities into the analysis of nuclear and chromosomal dynamics (van Holde, 1989; Miles, 1964, 1979).

Recent studies of chromosomes, utilizing fluorescent probes for chromosomal “painting,” suggest that the chromosomes **retain their distinct identity during the interphase** and that their position in the nucleus may be relatively constant throughout the life of the cell (Nagele et al, 1995; Koss, 1998).

CHROMOSOME STRUCTURE

Soon after a chromosome becomes visible in the early part (prophase) of mitotic division, it is already doubled into a pair of **identical chromatids** (Fig. 4-2A). This pair remains joined together at one point, the **centromere** (also called the *primary constriction*). The centromere divides the chromosome into a **short (from French, p = petit) and a long (q, the next letter after p) arm**

P.82

region. The centromere connects the chromosome to the spindle fibers during mitotic division. Associated with the centromere are proteinaceous structures, known as **kinetochores**, to which the microtubules of the spindle mechanism are attached (see below). Normal chromosome ends are capped by **telomeres**. These short repeat DNA **sequences are essential for maintaining the structural integrity of the chromosome** by preventing the ends from fusing with other chromosomes. If the telomere sequences are lost or broken off, an end-to-end fusion of two chromosomes can occur.

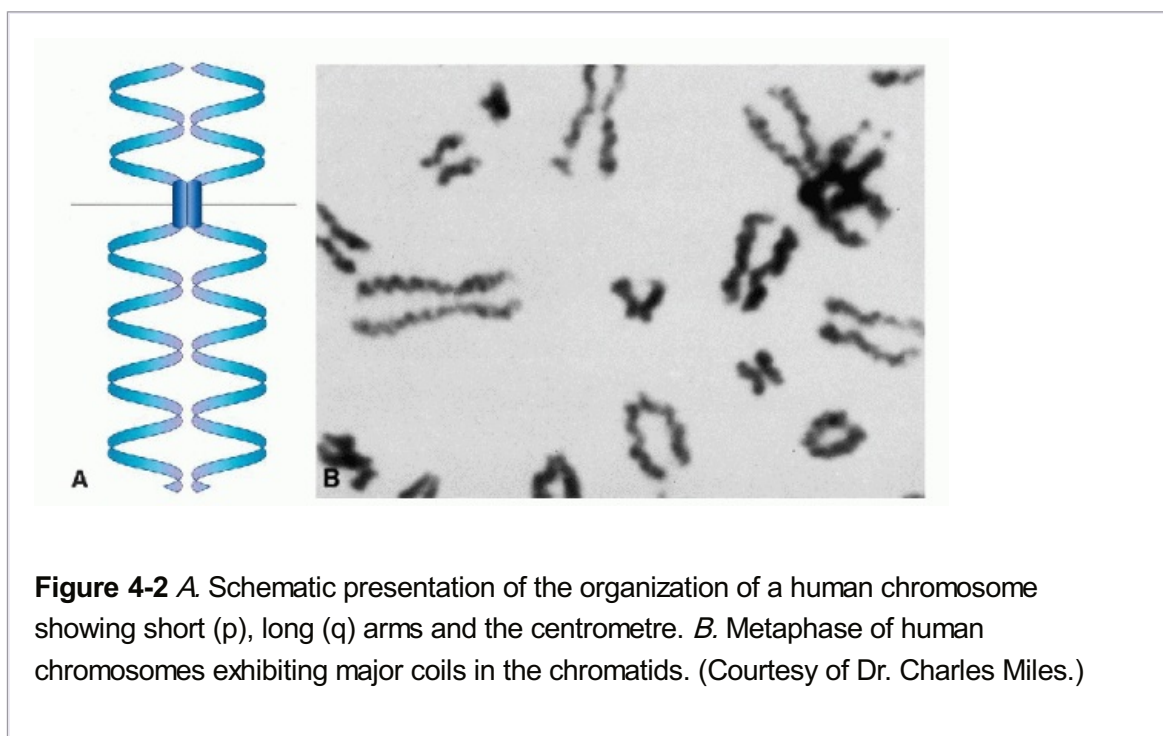

Figure 4-2 A. Schematic presentation of the organization of a human chromosome showing short (p), long (q) arms and the centromere. B. Metaphase of human chromosomes exhibiting major coils in the chromatids. (Courtesy of Dr. Charles Miles.)

In suitable preparations, it is clear that each chromatid is in the form of a single helical coil, sometimes referred to as the **major coil** (see Fig. 4-2B). In some plant species, the strand making up the major coil is composed of smaller or **minor coils** (i.e., the chromatid is a **coiled coil**). It is to be noted that the minor coil is too large to be the Watson-Crick double helix of DNA, which may be found as fine strands at the next level of resolution. The chromosomal structure at metaphase would consist of two chromatids, each of which is coiled-coiled coil, the smallest coil being the DNA double helix. This is a useful model to keep in mind, but it may represent an oversimplification. Electron micrographs of whole human chromosomes at metaphase exhibit what has been called a *folded fiber structure*, in which the fibers appear sharply but randomly bent or angulated into meshwork (Fig. 4-3). These fibers, assuming there is a protein coat, are about the right dimensions for DNA molecules. The evidence appears to be consistent with the view that each chromatid represents a tangle of single-strand DNA, forming the Watson-Crick double helix (Fig. 4-4) (Dupraw, 1966; Miles, 1964; Bahr, 1977; Therman, 1993). There are several theories pertaining to the relationship of the primary DNA molecule to the organization of the chromosome and chromosomal banding. An example of this proposal by Comings is shown in Figure 4-5.

STAGES OF MITOSIS

Living things grow and maintain themselves in large measure because their cells are capable of multiplying by successive division. The steps observed in nuclear division are called **mitosis** or, more precisely, **mitotic division**. Although the stages of nuclear division are not sharply demarcated, they are conveniently referred to as:

- prophase
- prometaphase
- metaphase
- anaphase
- telophase (Fig. 4-6; see Fig. 4-1)

Mitosis is a complex process, which includes a break-down of the nuclear envelope, chromatin condensation, and chromosome segregation. A brief description of these stages will first be given to provide a framework for a more detailed discussion.

Prophase proceeds from the first visible signs of cell division until the breakdown of the nuclear envelope. During the **prophase**, the **chromosomes have condensed** and appear as long rod-like structures. **Prometaphase** starts with the disruption of the nuclear envelope. **Metaphase** is the period during which the **chromosomes become aligned on the central metaphase plate**. **Anaphase** begins with the abrupt **separation of the chromatids into daughter chromosomes** as they proceed toward opposite poles of the cell. Finally, the nuclear membrane becomes reconstituted during **telophase**.

Figure 4-3 A. Electron micrograph of a whole mount of a human chromosome showing the A-folded fiber structure. The diameter of the fiber is about 20nm (200 Å). Reduced from the original magnification of $\times 28,000$. (Courtesy of Dr. Gunter Bahr, Armed Forces Institute of Pathology, Washington, D.C.)

Figure 4-4 Idealized schematic drawing of a human submetracentric chromosome at metaphase. Portions of the 2 spindle fibers are shown attached to the as yet unseparated centromere. Each chromatid exhibits a major coil but no finer structure can be seen with the light microscope.

Prophase

The transition from the G₂ phase to the M phase of the cell cycle is not a sharply defined event. The chromatin, which is diffuse in interphase, slowly **condenses into welldefined chromosomes**, the exact number of which is a characteristic of the particular species; each chromosome has duplicated during the preceding S phase and consists of **two sister chromatids** joined at a specific point along their length by the **centromere**. While the chromosomes are condensing, **the nucleolus** begins to disassemble and **gradually disappears**.

Within the nucleus itself, the first sign of prophase is an accentuation of the **chromocenters**

and a net-like pattern (Fig. 4-7B; see Fig. 4-6A). Several condensations of chromatin appear at the periphery of the nucleus, whence thin strands of chromatin extend into the center of the nucleus (see Fig. 4-7B). In females, the inactive X chromosome (Barr body) is larger than other chromocenters and is readily visible as a triangular condensation of chromatin (see Fig. 4-7). These strands and chromocenters are the condensing chromosomes. By this time, the chromosomes are probably doubled into the two chromatids or daughter chromosomes-to-be, but the double structure is sometimes difficult to visualize (Fig. 4-8A; see Fig. 4-6B). It is more evident in chromosomes that have been exposed to colchicine (a drug that inhibits mitosis) and which have been treated with **hypotonic salt solutions**. With the breakdown of the nuclear membrane, the chromosomes are quite distinct and are arranged into a circular position, known as a **hollow spindle** or **prometaphase rosette** (see below) (see Figs. 4-6C and 4-8B,C).

At the beginning of prophase, the **cytoplasmic microtubules**, which are part of the cytoskeleton (see Chap. 2), disassemble, forming a large pool of tubulin molecules. These molecules are then reused in the construction of the main component of the mitotic apparatus, the **mitotic spindle**. This is a bipolar fibrous structure, largely composed of microtubules, that assembles initially outside the nucleus. The focus for the spindle formation is marked in most animal cells by the **centrioles** (see Chap. 2). The cell's original pair of centrioles replicates by a process that begins immediately before the S phase to give rise to **two pairs of centrioles**, which separate and travel to the opposite poles of the cell (see Fig. 4-6D). Each centriole pair now becomes part of a **mitotic center** that forms the focus for a radial array of microtubules, the **aster** (from Latin, *aster* = star). Initially, the two asters lie side by side, close to the nuclear envelope. By late prophase, the bundles of polar microtubules that interact between the two asters (seen as polar fibers in the light microscope) preferentially elongate and appear to push the two asters apart along the outer part of the nucleus. In this way, a **bipolar mitotic spindle** is formed.

Prometaphase

Prometaphase starts abruptly with the **disruption of the nuclear envelope**, which breaks up into membrane fragments that are indistinguishable from bits of endoplasmic reticulum (see Fig. 4-6C). These fragments remain visible around the spindle during mitosis. Specialized structures called **kinetochores** develop on either face of the centromeres and become attached to a special set of microtubules, called **kinetochore fibers** or **kinetochore microtubules**. These fibers radiate in opposite directions from the sides of each chromosome and interact with the fibers of the bipolar spindle. The chromosomes are thrown into agitated motion by the interactions of their kinetochore fibers with other components of the spindle.

Metaphase

In phase cinematography of living cells, the chromosomes may be seen to undergo slow to and fro writhing movements until they finally become aligned on an **equatorial plane**. This plane bisects the mitotic spindle. As a result of their prometaphase oscillations, arrangement of all the chromosomes is such that their centromeres lie in one plane. The kinetochore fibers seem to be responsible for aligning the chromosomes halfway between the spindle poles and for orienting them with their long axes at right angles to the spindle axis. Each chromosome is held in tension at the metaphase plate by the paired kinetochores, with their associated fibers pointing to opposite poles of the spindle (see Figs. 4-6D and 4-8D).

Figure 4-5 Single-stranded model of chromosomal structure. This suggests that a single DNAB protein (DNP) fiber, beginning at one telomere, folds upon itself to build up the width of the chromatid and eventually progresses to the opposite telomere without lengthy longitudinal fibers, with no central core and no half- or quarter-chromatids. The centromere region in this metacentric chromosome is depicted as the result of fusion of two telocentric chromosomes, with retention of the individual centromere regions. The fibers at the point of chromatid association briefly interdigitate. (Courtesy of Dr. D. Comings.)

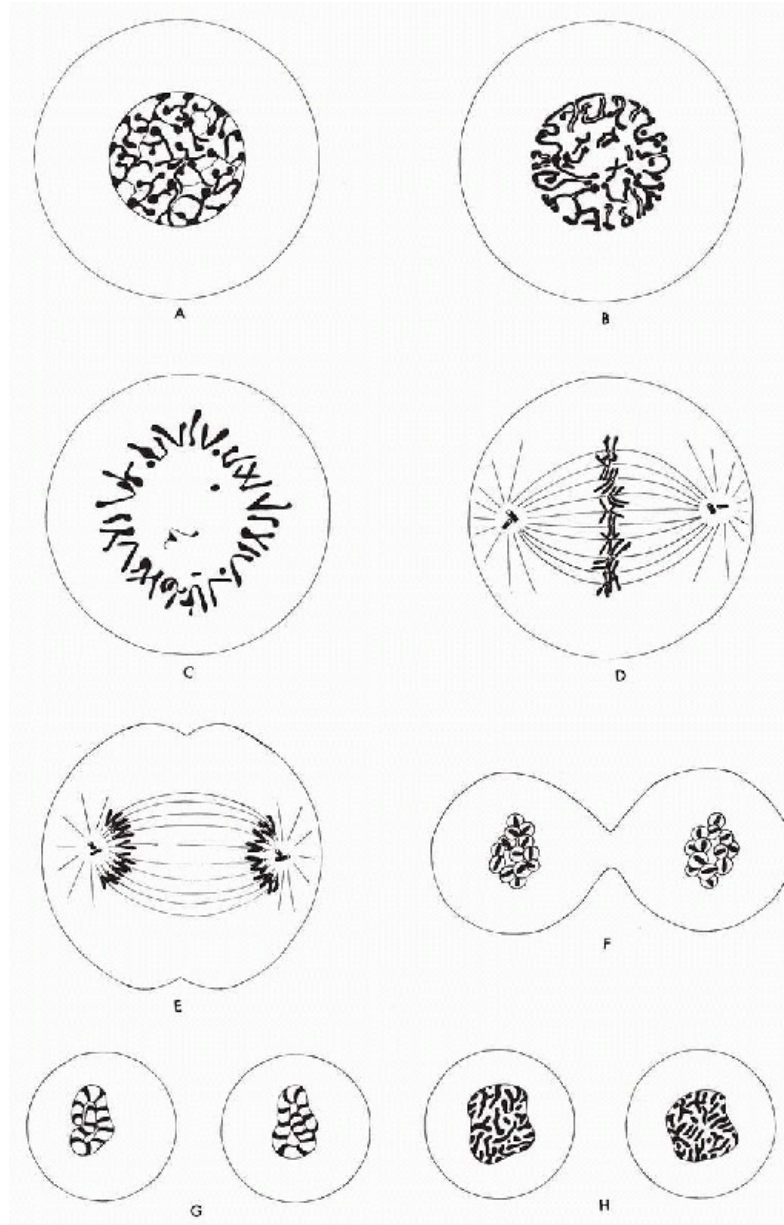

Figure 4-6 Diagrammatic presentation of human mitotic division. *A.* Mitosis begins with accentuation of the network pattern in the nucleoplasm and of the peripheral chromatin masses (chromocenters), which are presumably parts of the chromosomes. *B.* Further condensation of the chromosomes, some of which are now distinctly double (i.e., divided into chromatids). There is a breakdown of the nuclear membrane. *C.* At or shortly after the breakdown of the nuclear membrane (the conventional end of prophase), the chromosomes are arranged on the periphery of an equatorial plate, forming a so-called hollow spindle (it is not clear, however, that the spindle has as yet formed). *D.* The spindle at metaphase, with the equatorial plate viewed on end. The relative size of the centrioles, shown here as small rods, is exaggerated. *E.* Late anaphase: The chromosomes have divided, and the daughter groups form compact masses at the two poles. A furrow has appeared in the cytoplasm, marking the onset of cytokinesis. *F.* Early telophase: Each chromosome appears to form a small vesicle. *G.* The vesicles fuse to form a convoluted tubule with chromosomes at right angles to the long axis. Where the tubule walls contact one another, they apparently break down, leaving a continuous nuclear membrane around the chromosomes. *H.* In the final recognizable stage of telophase, the nucleus tends to

resemble prophase, with chromosomes still partly condensed. The convoluted appearance is still evident. (Courtesy of Dr. C.P. Miles.)

P.87

An early stage of prophase showing accentuation of the chromatin network and of the peripheral chromocenters. (*C,D*) A somewhat later stage of prophase. The same nucleus photographed at two focal levels. (*A,B*, $\times 3,900$; *C,D*, $\times 4,350$). (From Miles CP. Chromatin elements, nuclear morphology and midbody in human mitosis. *Acta Cytol* 8:356-363, 1964.)

Anaphase

The metaphase may last for several hours. As if triggered by a special signal, anaphase begins abruptly as the **paired kinetochores on each chromosome separate**, allowing each chromatid to be pulled slowly toward a spindle pole (see Fig. 4-6E). All chromatids are moved toward the pole they face at the same speed. During these movements, **kinetochore fibers shorten** as the chromosomes approach the poles. At about the same time, the **spindle fibers elongate** and the two poles of the polar spindle move farther apart. Soon after separation, the chromosomes appear at both poles as dark-staining masses (see Fig. 4-8E). The anaphase stage typically lasts only a few minutes.

In the meantime, the cell has become elongated, and a constriction furrow begins to appear at the level of the metaphase equator (see Figs. 4-9A and Fig. 4-6F). This process of cytoplasmic division is called **cytokinesis**. Although cytokinesis usually follows chromosomal division, the two processes are not necessarily dependent on one another. **Chromosomal division may occur without cytokinesis** (thereby producing a cell with double the normal complement of chromosomes). Less commonly, in some lower species, anucleated cytoplasm may undergo successive divisions.

The constriction furrow extends between the two daughter cells until only a narrow strand of cytoplasm is left. At this point, a distinct granule, the **midbody**, may sometimes be seen at the narrowest part of the cytoplasmic strand (see Fig. 4-9B). The midbody is formed, at least in part, by the spindle fibers compressed into a tight bundle. The precise significance and fate of the midbody are not known.

Telophase

Some details of telophase are worthy of attention. In late anaphase, after or during cytokinesis, the compact mass of chromosomes begins to swell. In optimal material, each chromosome appears to form a distinct small vesicle, possibly by inducing the formation of a proprietary segment of the nuclear membrane, as suggested by Koss (1998) (Fig. 4-10; see Fig. 4-6F). In abnormal divisions, the process may sometimes end at this stage, with the cell thus containing numerous micronuclei (Fig. 4-11). Normally, the vesicles seem to fuse rapidly together to form a convoluted tubule (see Figs. 4-12 and 4-6G). Probably the vesicle and tubule membranes break down at points of contact so that, ultimately, a continuous nuclear membrane is formed around both groups of daughter chromatids.

P.88

Figure 4-8 *A.* Late prophase, just before the breakdown of the nuclear membrane. The double structure can be visualized in some of these chromosomes. *B.* Nearing metaphase, the chromosomes show further contraction and (*C*) tend to congregate toward the periphery of the figure ("hollow spindle" arrangement). *D.* Chromosomes aligned on the metaphase plate. Note the spindle fibers converging on the centrioles. *E.* Late anaphase groups of daughter chromosomes. (*A*, $\times 2,220$; *B*, $\times 3,450$; *C, D*, $\times 3,150$; *E*, $\times 3,120$; *D, E*, phase contrast.) (From Miles, CP. Chromatin elements, nuclear morphology and midbody in human mitosis. *Acta Cytol* 8:356-363, 1964.)

Figure 4-9 *A.* Division of the cytoplasm (cytokinesis). *B.* Later stage of cytokinesis. The midbody is the small central granule (phase contrast $\times 1,560$). (From Miles, CP. Chromatin elements, nuclear morphology and midbody in human mitosis. *Acta Cytol* 8:356-363, 1964.)

Figure 4-10 Beginning of telophase reconstruction. Each chromosome appears to form a small vesicle. The dark double structure at the center of the spindle conceivably represents a divided midbody (phase contrast $\times 2,250$). (From Miles, CP. Chromatin elements, nuclear morphology and midbody in human mitosis. *Acta Cytol* 8:356-363, 1964.)

Figure 4-11 Abnormal mitosis with micronuclei, presumably formed through failure of chromosomal vesicles to coalesce (colchicine-treated culture; aceto-orcein stain $\times 1,610$). (From Miles, CP. Chromatin elements, nuclear morphology and midbody in human mitosis. *Acta Cytol* 8:356-363, 1964.)

The elongating chromosomes now appear at right angles to the tubule walls, thus to some extent, mimicking prophase appearances (see Figs. 4-13, 4-6H, and 4-12B). The outline of the nucleus gradually becomes less convoluted, and nucleolar material appears at the inner edges of the nucleus. The reticular appearance of the telophase nucleus (Fig. 4-14) gradually fades into the less-distinct interphase pattern.

Figure 4-12 Vesicles coalescing into tubules. A. Note chromosomes arranged at right angles to the long axis of the tubule (aceto-orcein stain $\times 1,120$; B, 1,610). (From Miles, CP. Chromatin elements, nuclear morphology and midbody in human mitosis. *Acta Cytol* 8:356-363, 1964.)

As the separated daughter chromatids arrive at the poles, the kinetochore fibers disappear. The polar fibers elongate still farther, the condensed chromatin expands once more, the nucleoli begin to reappear, and the mitosis comes to an end.

Cytokinesis

As described above, the cytoplasm divides by a process known as *cleavage*, which usually starts sometime during late anaphase or telophase. The membrane around the middle of

P.91

the cell, perpendicular to the spindle axis and between the daughter nuclei, is drawn inward to form a **cleavage furrow**, which gradually deepens until it encounters the remains of the mitotic spindle between the two nuclei (see Figs. 4-6F and 4-9). This narrow bridge, which contains a dark granule, the **midbody**, may persist for some time before it finally breaks at each end, leaving two completed, separated daughter cells (Miles, 1979; Alberts, 1983; Brachet, 1985; Levitan, 1988; Edlin, 1990; Therman, 1993).

Figure 4-13 Late stages of telophase beginning to mimic prophase appearance.

One daughter nucleus still shows tubule structure (aceto-orcein stain, $\times 3,150$). (From Miles, CP. Chromatin elements, nuclear morphology and midbody in human mitosis. *Acta Cytol* 8:356-363, 1964.)

Figure 4-14 Telophase. The daughter nuclei still appear somewhat convoluted, but no suggestion of tubule remains. (Part of an interphase nucleus impinges on one daughter nucleus.) Some of the spoke-like chromosomal elements appear distinctly double, as does the larger bipartite chromocenter in one nucleus (the sex chromatin body?) (aceto-orcein stain $\times 2,520$). (From Miles, CP. Chromatin elements, nuclear morphology and midbody in human mitosis. *Acta Cytol* 8:356-363, 1964.)

THE NORMAL HUMAN CHROMOSOME COMPLEMENT

Before 1956, the number of human chromosomes was believed to be 48, and the XX-XY

mechanism of sex determination was assumed to work in the same way as it does in the fruit fly, *Drosophila*. Both of these notions about human chromosomes were eventually proved wrong. The year 1956 is often given as the beginning of modern human cytogenetics; indeed, the discovery by Tjio and Levan in 1956 that the **human chromosome number is 46** (Fig. 4-15), and not 48, was the starting point for subsequent spectacular developments in human cytogenetics. Contemporary techniques (use of colchicine/colcemid, culture methodologies, hypotonic treatment) confirmed that normal human cells have 46 chromosomes, **two sex chromosomes** (X,X or X,Y) **and 44 autosomes**. These can be seen and classified in the metaphase stage of cell division.

In 1970, Caspersson and his colleagues applied fluorescence microscopy, which they had originally used to study plant chromosomes, to the analysis of the human karyotype. They discovered that the chromosomes consist of differentially fluorescent cross bands of various lengths. Careful study of these bands made possible the identification of all human chromosomes. This discovery was followed by a host of different **banding techniques**. The most commonly employed technique is **trypsin or G-banding** (see Fig. 4-15). Chromosome preparations are pretreated with trypsin before staining them with Giemsa stain (hence, Giemsa or G-banding). By means of such banding, **each chromosome (homologue) can be identified** by the resulting alternating light and dark band patterns specific to that particular chromosome. Another banding procedure, which gives only slightly different results, involves staining with a fluorescent dye, **quinacrine dihydrochloride**, which thus yields quinacrine or **Q-bands**. These bands fluoresce under ultraviolet light with varying degrees of brightness, similar to the light and dark bands produced by G-banding. The banding of elongated prophase or prometaphase chromosomes makes it possible to define chromosome segments and breakpoints even more accurately (Bergsma, 1972; Yunis, 1974; Hsu, 1979; Emery and Rimoin, 1983; Mange and Mange, 1990). The **C-banding technique** is used to highlight the constitutive chromatin region of the chromosomes, usually the centromeres and the long arm of chromosome Y. The chromosomal preparations are exposed to barium hydroxide-saturated solution and stained with Giemsa.

With the exception of the sex chromosomes X and Y, the chromosomes occur in pairs, each pair composed of two identical chromosomes or **homologues** (from Greek, *homo* = same). Each pair of chromosomes has been numbered from 1 to 22 in order of length. The pairs are further divided into seven subgroups designated 1-3, 4-5, 6-12, 13-15, 16-18, 19-20, 21-22, or by letter A, B, C, D, E, F, and G, respectively (Fig. 4-16; see Fig. 4-15). The centromere, or primary constriction, is in a constant position on any given chromosome. In the terminology commonly employed for human chromosomes, the chromosome is **metacentric if the centromere is located at the center of the chromosome**, thus making both arms equal in length; a chromosome is **submetacentric if one arm is longer than the other**; a chromosome is **acrocentric (acro = end) or subtelocentric if the centromere is located very close to the end of the short arm**.

Figure 4-15 A. G-banded metaphase spread of a normal male cell. B. G-banded karyotype of a normal male cell showing the band characteristics of each pair of homologues, as well as the sex chromosomes (X and Y).

P.93

The pairs of chromosomes at metaphase can be accurately classified into the **seven groups** by using the characteristics of length and centromere position. The two groups of acrocentric chromosomes, D (13-15) and G (21-22), for example, are easily identifiable, especially in colchicine-treated preparations. Colchicine prevents (among other effects) the centromere from dividing but does not interfere with chromatid separation. Thus, the acrocentrics remain joined at one end and come to resemble a wishbone or an old-fashioned clothespin. However, distinguishing chromosomes within groups was difficult and, sometimes impossible, until banding techniques were discovered.

Additions or deletions of portions of the chromosomes are designated by chromosome numbers and band numbers followed by p or q and + or - signs. In this

manner, a precise identification of chromosomal segments, which are missing, added, or translocated can be achieved. Specialized nomenclature has been established to denote changes in chromosome number and structure (ISCN, 1995).

The ability to identify every chromosome by number has led to a slight change in the rule correlating number with chromosomal length. It has been found that the chromosome that accounts for Down's syndrome (see below) is, in fact, the shortest and not the next-to-shortest chromosome. However, to preserve the synonym **trisomy 21** for Down's syndrome, the shortest chromosome is designated as 21 and the next shortest chromosome is designated as 22.

Certain other chromosomal features, although not of great importance in identifying particular homologues, may ultimately be of significance in the study of pathology. **The long and short acrocentrics** (13-15 and 21-22 groups) often exhibit a small structure on the short arms, called a **satellite**. Satellites, when well visualized, consist of short, thin filaments surmounted by a tiny mass of chromatin. Satellites are close to the limits of resolution, and they can rarely be observed on all the acrocentrics within one cell. Failure to demonstrate them is probably due to technical difficulties. It is known, though, that some individuals show very **conspicuous satellites**, although, once again, not on all of the acrocentrics; there has been no convincing evidence that these larger satellites are related to any disease state.

Individual or familial differences may also be observed in the **size and centromere position** of chromosomes in normal persons. Size differences were first clearly shown for the **Y chromosome** (Sandberg, 1985a, 1985b).

In addition to cytogenetic techniques for identifying individual chromosomes and their bands, sub-bands, and structures (Fig. 4-17), techniques have been developed recently for **identifying chromosomes based on unique DNA sequences within each chromosome**. This approach allows the recognition of specific chromosomes, or their parts, in interphase nuclei, thus dispensing with the more laborious process of metaphase preparation, or in situations when metaphases cannot be obtained. **Fluorescent in situ hybridization (FISH)** with molecular "paint" probes to specific chromosomes and their components has become an established laboratory technique (see Fig. 2-31). It allows the analysis of cells and tissues for the presence of chromosomal abnormalities. However, detailed karyotype analysis still requires optimal metaphases for their construction (Cannizzaro and Shi, 1997; Montgomery et al, 1997).

Heterochromatin

Another feature of chromosomes that shows familial differences, probably unrelated to disease, is the **secondary constriction**. (The **primary constriction** is at the centromere where the spindle fibers attach during mitosis; see earlier.) Readily visible in the microscope are secondary constrictions in the long arms near the centromere on chromosomes 1, 9, and 16. In normal cells, these constrictions are seen only occasionally and seldom in more than one homologue in a given cell. These constrictions are usually observed near centromeric sites on most chromosomes. At these sites, most chromosomes have small blocks of chromatin that replicate their DNA after the other chromosomal segments have completed DNA synthesis (**e.g., late-labeling DNA**). Such sites can also be selectively stained with the C-banding technique, centromeric heterochromatic stain (Fig. 4-18). In many species, such dark-staining, late-labeling segments are referred to as **heterochromatin**. In some species, these segments do not decondense in the interphase nucleus but rather remain as dark-staining masses of chromatin called **chromocenters**. In general, such **heterochromatin segments are**

genetically inert (do not contain functioning genes and do not synthesize RNA). They are believed to have something to do with maintaining the structure of the chromosome; the material, therefore, is called **constitutive heterochromatin**. The latter is differentiated from **facultative heterochromatin**, which is condensed in some cells and not in others and, in contrast to constitutive heterochromatin, reflects some of the stable differences in genetic activity adopted by different cell types (e.g., embryonic cells seemingly contain very little, and some highly specialized cells contain a great deal of heterochromatin). Facultative heterochromatin is not known to contain the large number of highly repeated DNA sequences (satellite DNAs), which is characteristic of constitutive heterochromatin (Bahr, 1977; Lima-de-Faria, 1983; Therman, 1993). Although chromocenters (except for the sex chromatin body; see below) may vary in their appearance in the nuclei of human cells and, in some, they are difficult to visualize, only **polymorphonuclear leukocytes are an exception**. In the nuclear lobes of these cells, the constitutive heterochromatin of chromosome 1 and, perhaps other chromosomes, is observed as a **peripheral chromocenter**. With a somewhat similar technique, the C-band **heterochromatin of chromosome 9 can be identified in interphase nuclei of lymphocytes**.

P.94

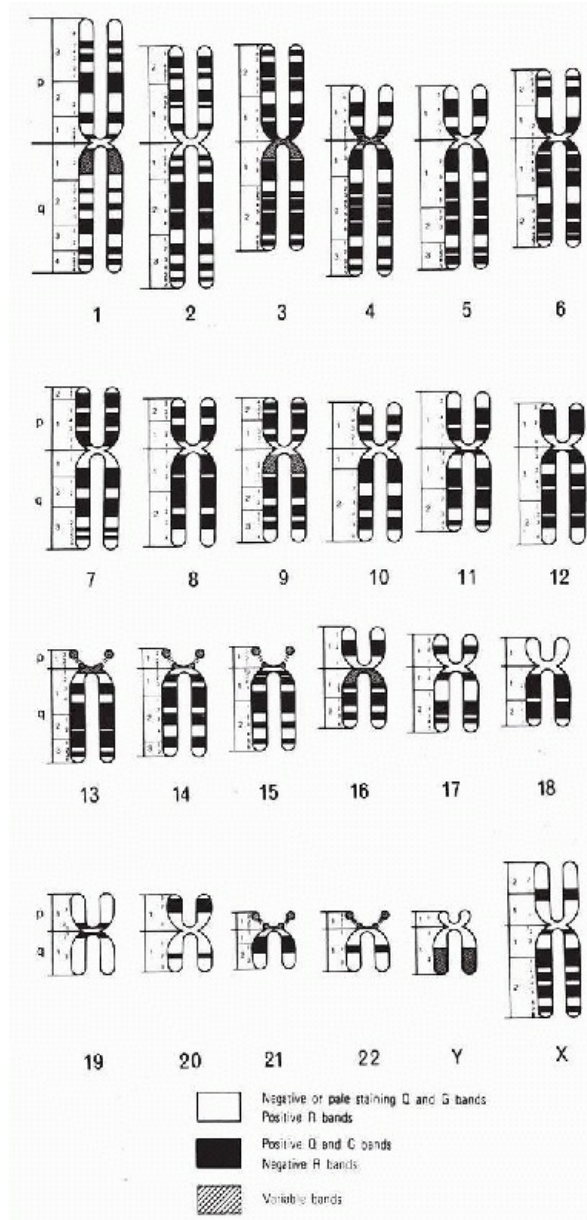

Figure 4-16 Ideogram illustrating Q- and G-bands in human chromosome complement. R-bands are the reverse of G-bands. The short arms of the chromosomes are designated as p and the long arms as q. (From Bergsma, D. [ed]. Paris Conference, 1971, Standardization of human cytogenetics. Birth Defects 8:7, 1972.)

Figure 4-17 Schematic presentation of the bands in the normal X chromosomes at different levels of staining resolution. The X chromosome of the *left* has 17 bands besides the centromeric one, the one in the *middle* has 26 bands, and the one on the *right* has 38 bands. The use of special methodology allows the resolution of some bands into sub-bands (e.g., band Xq23 into Xq23.1 B 3). (From ISCN. An international system for human cytogenetic nomenclature, Mitelman F (ed). Basel, Switzerland, S. Karger, 1995.)

Figure 4-18 C-banded karyotype of a normal female cell, with constitutive heterochromatin of the various chromosomes staining dark. Note in particular the relatively large C-bands in chromosomes 1, 9, and 16, with each showing polymorphism of these bands. The *inset* shows a Y chromosome from a male cell demonstrating the dark staining of its long arms with this procedure. (Courtesy of Dr. Avery Sandberg.)

GERM CELL FORMATION, MEIOSIS, AND SEX DETERMINATION

Germ Cell Formation

As has been stated, most human cells contain 46 chromosomes. The germ cells, sperm and ovum, constitute an important exception. Since the individual develops from the union of sperm and ovum, to preserve the proper somatic number of 46, these cells can have only 23 chromosomes each. Thus, the developing germ cell must lose half its chromosomes. The product of the union of the spermatozoon and the ovum, or the **zygote**, will then receive 23 chromosomes from the mother and 23 from the father. A type of cell division known as **meiosis** fulfills these requirements (Fig. 4-19).

It is clear that normal development will require that the zygote receive a set of similar chromosomes (e.g., one No. 1, one No. 2, and so on) from each parent. A set of 23 maternal or paternal chromosomes is a **haploid set**, and the final two sets of homologues form a **diploid set**.

Meiosis

The fundamental mechanism of meiosis serves to ensure that each germ cell acquires a precise set of 23 homologues, including **either an X or a Y chromosome**. Meiosis essentially consists of **two separate divisions, referred to as the first and the second meiotic divisions** (see Fig. 4-19).

First Meiotic Division

The prophase sequence of this division has been divided into several stages named **leptonema**, **zygonema**, **pachynema**, **diplonema**, and **diakinesis**. The chromosomes in **leptonema** (from Greek, *lepto* = thin and *nema* = thread) condense out as long convoluted threads. In **zygonema** (from Latin, *zygo* = pair), homologous chromosomes come together and pair, point for point, along their lengths. This process is called *synapsis of the homologues*, and the closely aligned synapsed pair is called a **bivalent**.

At the beginning of **pachynema** (from Greek, *pachy* = thick), pairing is complete, and the chromosomes become shorter and thicker. By this stage, each homologue may appear doubled into its two chromatids; hence, four units are seen, and the **bivalent** has become a **tetrad**. In **diplonema** (from Latin, *diplo* = double), the homologues begin to move away from one another, but they usually continue to remain joined at one or more points along their lengths. The involved segments near such points will resemble an X, or a cross, hence the name *chiasma* (plural, *chiasmata*) for such points.

In **diakinesis**, the tetrad continues to loosen, until at the

P.97

first meiotic metaphase, the homologues separate completely and pass to opposite poles.

Figure 4-19 Diagrammatic presentation of the stages of meiosis (spermatogenesis).
(Courtesy of Dr. C.P. Miles.)

Crossover

The appearance of chiasmata is associated with **the reciprocal exchange of segments of homologous chromatids** that had tightly synapsed together in the earlier stage. Perhaps this process can be more readily grasped if we visualize the paternal homologue as a single column of soldiers that becomes aligned with a similar column, the homologue of maternal origin. If a few of the soldiers simply exchange places with an equal number from the opposite group, the composition of each column becomes completely different, but the general appearance of the column remains unchanged. In genetic terms, a crossover has occurred, and each column now represents a new combination of soldiers (Fig. 4-20).

Chromosomal segments cannot be exchanged quite so readily as soldiers in a column, since breaks in the chromosomes are probably necessary, and each break apparently prevents the occurrence of a similar break in the near vicinity. Consequently, the synapsed chromosomes seldom exchange more than one or two segments. Thus, the final germ cell does not necessarily receive unaltered paternal or maternal homologues. **Many of its chromosomes will consist of rejoined segments from both parents.** Although the behavior of the X chromosome in female meiosis is similar to that of the autosomes, the behavior of the X and Y in male meiosis is an exception to the rule. **The X and Y chromosomes in the developing spermatocyte do not synapse together** and, consequently, do not exchange segments by crossing over. Instead, the human X and Y chromosomes pair at the distal

P.98

ends of their short arms during male meiosis. There is formation of a synaptonemal complex between X and Y chromosomes in this region. Recent molecular studies have shown that there is DNA homology between X and Y chromosomes at their distal short arms, where there is a single obligatory crossing over between X and Y during meiosis. As a result, loci mapping in this region do not show strict sex linkage; accordingly, this homologous segment of the X and Y chromosomes is referred to as the **pseudoautosomal region** (Sandberg, 1983a).

Figure 4-20 Schematic presentation of crossover of genetic material during first meiotic division. (Courtesy of Dr. C.P. Miles.)

Second Meiotic Division

The second meiotic division is much more akin to a somatic or mitotic division, with separation of the chromatids. All of the resulting daughter cells are haploid, that is, contain 23 chromosomes. As a result of crossing over in meiosis I, the genetic content of each haploid cell is a mixture of paternal and maternal genes.

Meiosis not only serves the fundamental need of reducing the chromosomal number of the germ cells but also constitutes a kind of lottery that vastly increases the possibilities for genetic variation. Not only does each germ cell draw at random one or the other homologue, but these homologues may themselves have already been altered through reciprocal exchange of segments. Meiosis is the principal reason for the enormous diversity, even among members of the same family (Roberts and Pembrey, 1985).

Sex Determination

The **sex chromosomes**, the male Y and the female X, differ from the **nonsex chromosomes or autosomes**. Whereas the female has two X chromosomes, the male has only one X and one Y. During the process of meiosis, each germ cell ends up with a precise haploid set of autosomes. **In sperm, each haploid set will also include either an X or a Y chromosome.** Thus, by chance, roughly 50% of sperm will bear an X and 50% a Y. Since the mother has only one kind of sex chromosome, **all of the ova contain a single X.** If an ovum is fertilized by an X-bearing sperm, a female zygote will result (46,XX); if by a Y-bearing sperm, the offspring will be male (46,XY). Thus, it is the paternal chromosome that determines the sex of the child (Ohno et al, 1962; Miles, 1979; Levitan, 1988; Mange and Mange, 1990).

Chromosomal Nondisjunction

Mitosis and meiosis are not perfect mechanisms. Occasionally, homologous chromosomes or chromatids will fail to disjoin from one another (Fig. 4-21). This results in the two chromosomes migrating to the same pole rather than to different poles. This process is known as *nondisjunction*. **Numerical abnormalities** in the form of either additional or fewer chromosomes in the daughter cells **are a result of such chromosomal misdivisions.**

THE SEX CHROMATIN BODY AND ABNORMALITIES OF SEX CHROMOSOMES

In 1952, Barr and Bertram noticed that, in some neuronal nuclei of a cat's brain, a tiny dark granule migrated from the nucleolus to the nuclear membrane in the course of reaction to injury. These investigators noted that the dark granule appeared in some animals but not in others and, by checking their records, found that the tiny granule was found only in female and not in male cats. It was soon established that this difference extended to other tissues and to other mammals, including humans. The granule is now known as the **sex chromatin body** or as a **Barr body** and **represents a condensed X chromosome** (see Fig. 4-7A).

The significance of this finding for the study of abnormal sexual development was not lost on investigators who began to examine various types of patients with abnormalities of the sex chromatin body. One relatively common type is **Klinefelter's syndrome**, a condition in males that includes a slender body build, infertility, small testes, and, occasionally, gynecomastia. In cells of about 90% of such patients, a sex chromatin body was observed. It was thought initially that patients with Klinefelter's syndrome were genetic females. Subsequent cytogenetic analysis disclosed that most of these patients had a supernumerary sex chromosome, with a 47,XXY karyotype (Fig. 4-22).

The opposite situation was observed in patients with **Turner's syndrome or gonadal dysgenesis**. These patients are **females at birth** but have a poor development of secondary sex characteristics and fail to menstruate at puberty. Other stigmata of Turner's syndrome include a **webbed neck, a wide angle of the forearms, pigmented**

P.99

nevi, and coarctation of the aorta. In the cells of the presumed females with this syndrome, the sex chromatin body could not be found and the patients were thought to be genetic males. Cytogenetic analysis disclosed that the majority of **these patients lack one X chromosome** and that the **karyotype is 45,X** (see Chap. 8). In the remaining patients with this disorder, still **other chromosomal abnormalities may be observed.** Thus, some patient's cells may contain a normal X plus an X in which a part of the short or long arm has been deleted. In other cases, the abnormal X may contain, in lieu of the short arm, an additional long arm. **Such chromosomes with two identical homologous arms are called isochromosomes.**

Moreover, both in Turner's syndrome and in other cases of gonadal congenital abnormalities, the **chromosome complement may differ from cell to cell**, one cell line being (for example) normal 46,XX and another cell line with a 45,X complement, resulting in **mosaicism**. There are many more complex examples of mosaicism on record. The clinical appearance or phenotype of such patients varies markedly, but the complexities are too numerous to be discussed here. For further comments on Turner's syndrome and its recognition in cervico-vaginal smears, see Chapter 9.

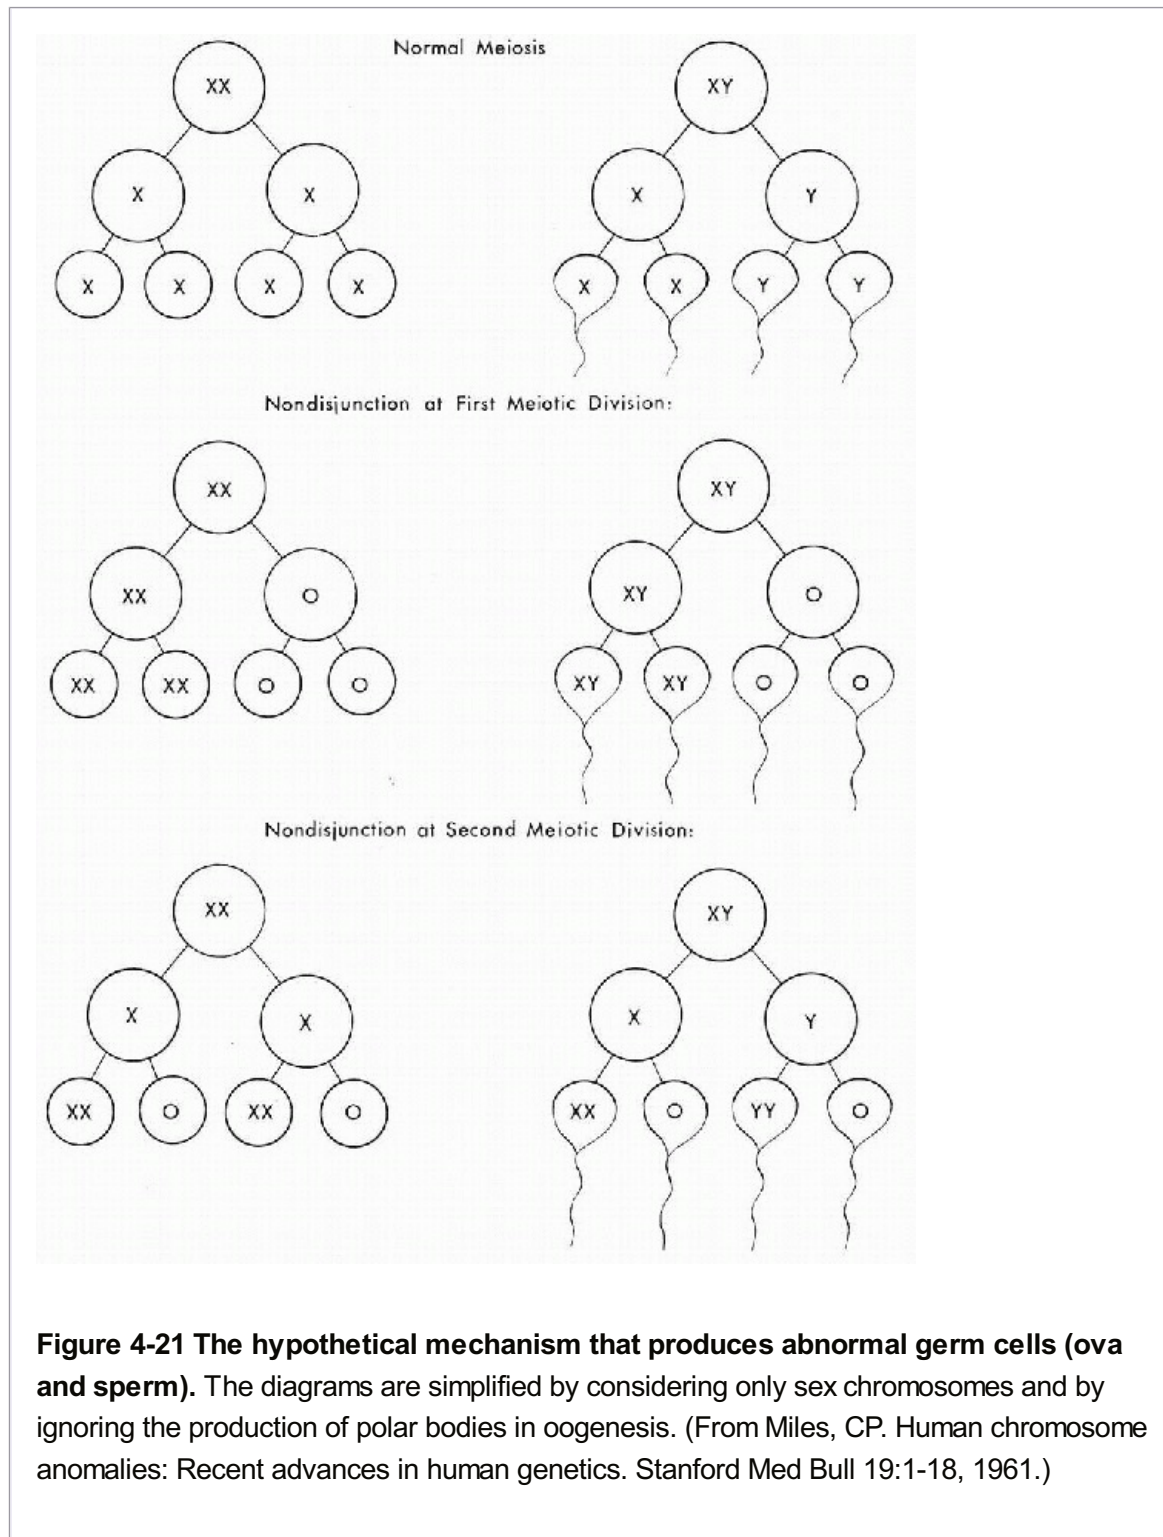

Figure 4-21 The hypothetical mechanism that produces abnormal germ cells (ova and sperm). The diagrams are simplified by considering only sex chromosomes and by ignoring the production of polar bodies in oogenesis. (From Miles, CP. Human chromosome anomalies: Recent advances in human genetics. Stanford Med Bull 19:1-18, 1961.)

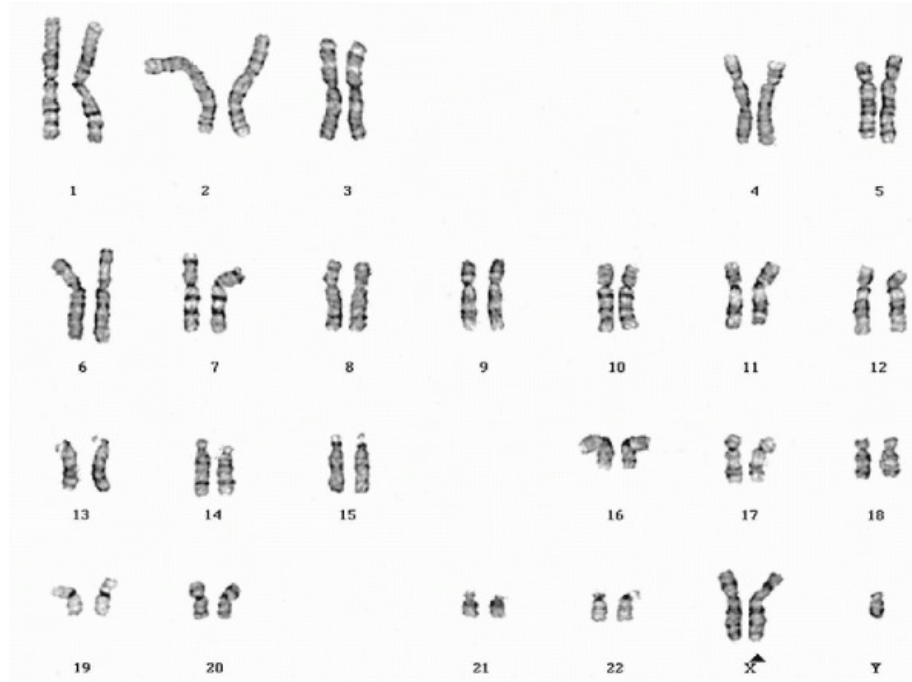

Figure 4-22 Karyotype of a male with Klinefelter's syndrome or 47, XXY. The arrowhead points to an additional X chromosome.

These and similar discoveries stimulated intensive analyses of patients with sexual maldevelopment. Moreover, with the knowledge that patients with Klinefelter's syndrome were occasionally somewhat mentally defective, surveys were conducted on patients in mental institutions and prisons. These surveys revealed, not only more cases of XXY, but also cases of XXXY and XXXXY. Such **male individuals with three and four X chromosomes tend to show a more severe mental deficiency** and may have skeletal and other abnormalities.

Figure 4-23 Nucleus from a female with a 46, XXX karyotype showing two sex chromatin or inactivated X chromosomes instead of the usual one present in normal (46,XX) females.

Women with three (Fig. 4-23), four, five, and even

P.101

more X chromosomes have been described (Fig. 4-24). Those with three X chromosomes have been referred to as *superfemales* or allusion to a comparable situation in the fruit fly, *Drosophila*. However, the term, *super* refers strictly to the chromosomes, since in humans such **women are virtually normal**. Even with four X chromosomes, there may be only slight menstrual irregularities. There is some tendency to mental deficiency, however, and patients with five X chromosomes are usually severely retarded (Miles, 1961; Ohno et al, 1962; Moore, 1966; Sandberg, 1983a, 1983b, 1985a, 1985b; Schinzel, 1984; Mange and Mange, 1990).

With Q-staining, **the Y chromosome** is very **brightly fluorescent** and forms the so-called **Y-body** in interphase nuclei. Y-bodies can be demonstrated in a wide variety of cell types, including buccal mucosa, lymphocytes, and amnion cells. The most common anomaly of the Y chromosome is the XYY syndrome.

Figure 4-24 Female cells in tissue culture showing 2, 4, 8, and 16 sex chromatin bodies (tetraploid, octaploid, 16-, and 32-ploid cells). The sex chromatin bodies are concentrated in a single segment of the cell membrane. (From Miles CP. Prolonged culture of diploid human cells. *Cancer Res* 24:1070-1081, 1964.)

Origin of the Sex Chromatin Body

The finding of individuals with three or more X chromosomes has shed definitive light on the origin of the sex chromatin body. The cells of individuals with three X chromosomes have, at most, two sex chromatin bodies; individuals with four X chromosomes have at most three; and with five Xs, there are at most four sex chromatin bodies per cell. Thus, the maximum number of **sex chromatin bodies per cell is always one less than the number of X chromosomes**. This conforms to a theory proposing that the sex chromatin body consists of most, or all, of a single X chromosome. Since we know that, after the very early stage of sex determination in the fetus, only one X is necessary for normal development, it is plausible that the other or others become and remain condensed (fixed differentiation) in the somatic cells. The process of

random inactivation of one of the X chromosomes, first postulated by Lyon, is called **lyonization**, and the affected

P.102

chromosome is presumed to be inert, not participating in the manufacture of RNA.

The chromatin that makes up the sex chromatin body is referred to as **facultative heterochromatin** as opposed to **constitutive heterochromatin** (see above), which occurs in large or small blocks near the centromeres of all chromosomes and which, so far as is known, is a permanent feature of the chromosome in all stages of development, including mitosis and meiosis. Facultative heterochromatin, on the other hand, appears in one or the other X chromosome, at random, in females at about the blastula stage.

Extra Sex Chromatin Bodies in Polyploid Cells

It may be worth pointing out that one may occasionally observe extra sex chromatin bodies in basically normal tissues. This is caused by **doubling of the entire chromosomal complement (tetraploidy)**. Each X chromosome will be doubled, but the differentiation of the two Xs was previously fixed; hence, despite four X chromosomes, there will be only two, not three, sex chromatin bodies. Extreme degrees of **chromosomal duplication or polyploidy** may occur by virtue of this doubling mechanism. It is also of note that extra sex chromatin bodies may be a useful guide in identifying cancer cells with abnormal chromosomal content. Thus, as discussed in Chapters 7, 12, and 29, finding an extra Barr body in a suspect cell supports the possibility that the cell is malignant.

Figure 4-25 Karyotype of a male with Down's syndrome or 47,XY, + 21. The extra chromosome 21 is indicated by the arrowhead.

ABNORMALITIES OF AUTOSOMES

Down's Syndrome (Trisomy 21)

Abnormalities involving sex chromosomes are neither the most common nor the most serious of chromosomal abnormalities. Of those that involve autosomes, the most important, at least in terms of incidence, is **Down's syndrome**. Down's syndrome is characterized by **severe mental retardation**, characteristic facial and other physical abnormalities, and is almost always related to an extra small acrocentric (G-group) chromosome 21, resulting in a karyotype with 47 chromosomes (Fig. 4-25).

In a small percentage of cases of Down's syndrome, the extra chromosome may become attached to another long acrocentric (D-group) chromosome. Less commonly, it may

P.103

become attached to another G-group chromosome. **The attachment of one chromosome or a portion of one chromosome to another chromosome is referred to as a translocation**, and such cases are referred to as *translocation Down's syndrome*. The distinction is important since simple trisomy 21 occurs sporadically, although with an increased incidence in children of older mothers.

Translocation **Down's syndrome**, on the other hand, **often occurs in families** since the abnormal chromosome may be passed on from a parent to the offspring. Cases of Down's syndrome have also been described in which the karyotype appears normal. In some of these, however, there is suggestive evidence that a small portion of a G-group chromosome has been translocated; the segment is simply too small to be detected cytogenetically but can be detected with molecular techniques. A number of cases have been described that involve deletions or **total absence (monosomy) of a G-group chromosome**. These result in severe mental retardation and other abnormalities but are not so distinctive as Down's syndrome. Children with Down's syndrome have **an increased risk of leukemia, especially acute leukemia**.

Other Trisomy Syndromes

Patients with abnormalities involving other autosomes are less common, and the resultant abnormalities are more variable. An additional E group chromosome 18 results in **trisomy 18 or Edwards syndrome**. Such patients demonstrate abnormalities of the central nervous system and other quasispecific features, such as low-set ears, small jaw, and flexion deformities of the limbs. These infants seldom survive beyond 1 year.

An additional D-group chromosome 13, is known as **trisomy 13 or Patau syndrome**. Patients demonstrate more severe congenital defects than trisomy 18 patients. Such infants are born with an underdeveloped brain and eyes, cleft palate, extra digits, and cardiac abnormalities. They seldom survive beyond a few weeks of life.

In both trisomy 13 and 18, the extra chromosomes may be translocated and fixed onto another homologue in the karyotype. With the newer banding techniques, trisomies have been reported involving chromosomes 8 and 9 or portions of chromosomes 7, 8, 9, and 10 (**partial trisomies**) and others. All of these involve severe mental retardation with a variety of other congenital abnormalities.

Chromosomal Deletion Syndromes

Total absence (monosomy) of **autosomes**, larger than those in the G group, is probably incompatible with fetal development to term. Loss of part of the short arm of **chromosome 5** results in the so-called **cat-cry (cri-du-chat) syndrome**. Apart from the unusual cry in infants,

this syndrome does not have any of the characteristic clinical features typical for the trisomy syndromes 21, 13, and 18. These children, who are mentally deficient, may survive for some years. **Deletion of the short arm of chromosome 4** is less common and leads to more severe anomalies. Congenital abnormalities associated with deletions of various autosomes have been described. If portions of both the long and short arm of the same chromosome are deleted, **the ends may heal together and form a ring (ring chromosome)** with developmental abnormalities similar to those with simple deletions.

Figure 4-26 Metaphase spread of fluorescent in situ hybridization analysis of patient suspected of having Williams syndrome or deletion 7q11. The green signal on each chromosome is hybridization to a chromosome 7-specific sequence. The red signal on both chromosomes is the signal from the ELN gene probe. In this case, the patient did not contain the ELN gene deletion and did not have Williams syndrome.

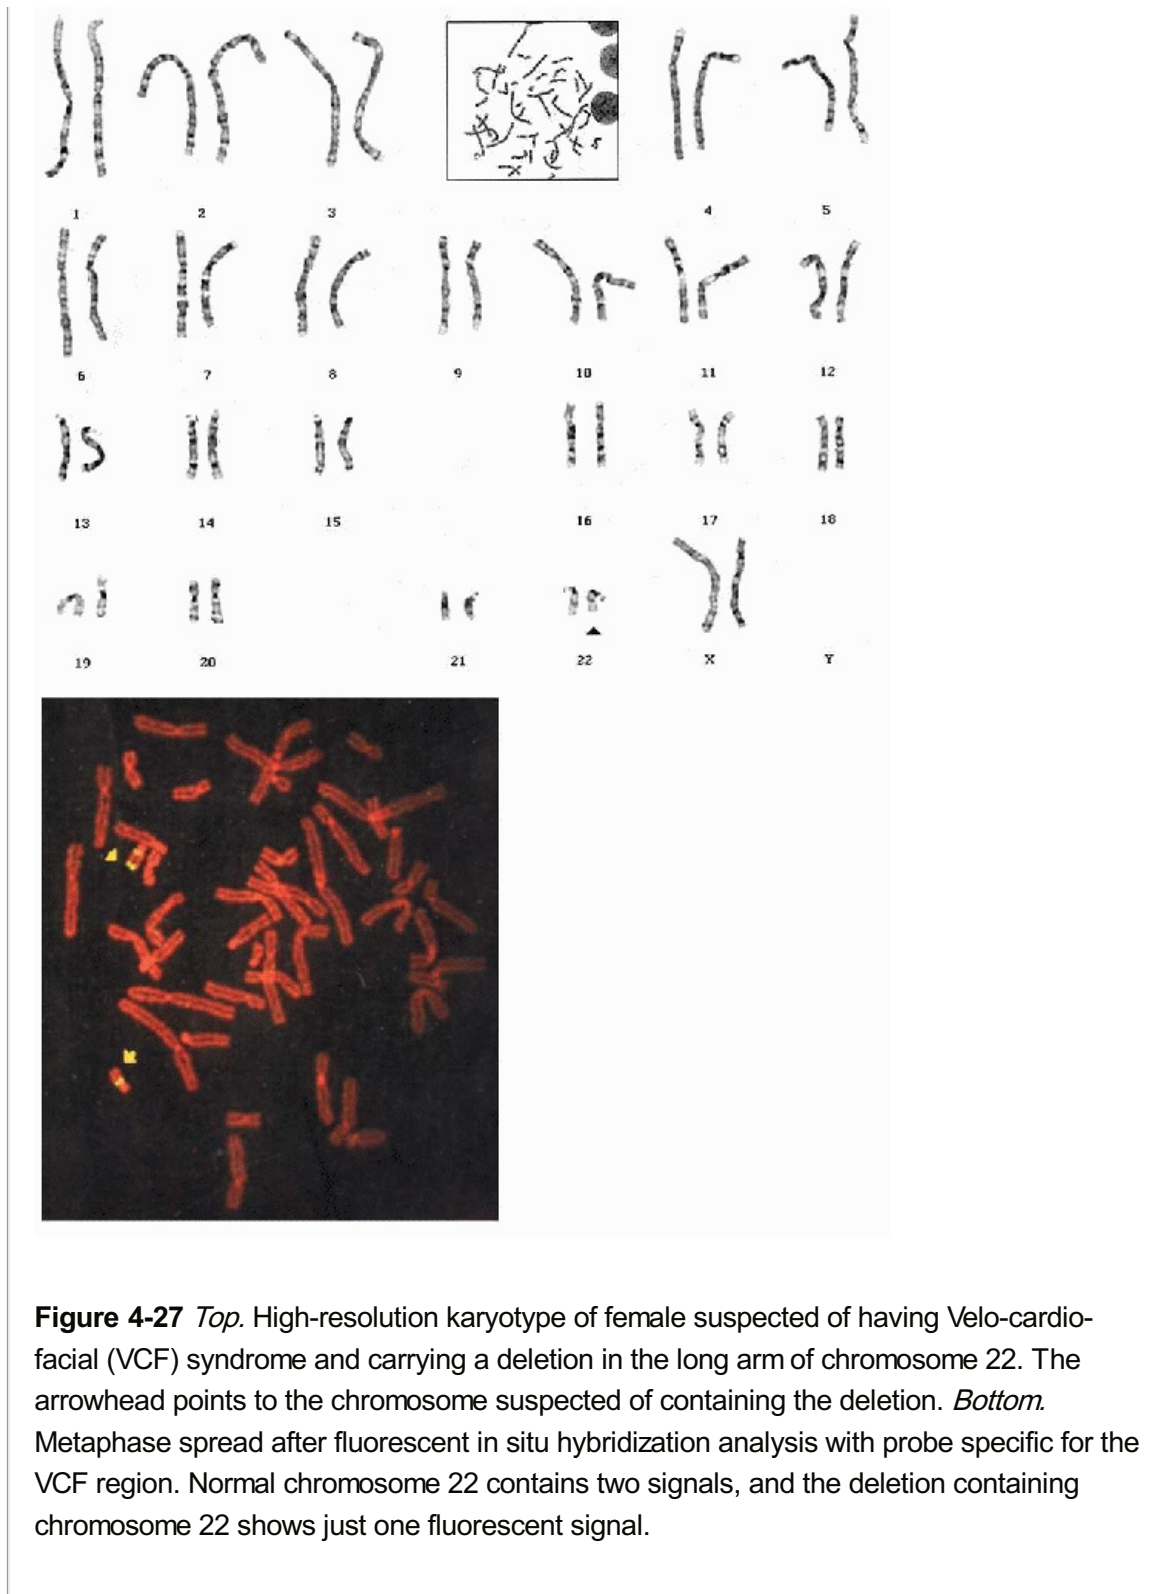

Microdeletion Syndromes

Detection of some deletions is beyond the resolution of standard cytogenetic analysis. The genes responsible for a specific syndrome such as **Williams syndrome** where the elastin (ELN) gene is deleted, are not resolvable at the cytogenetic level, even by high-resolution chromosome analyses. In such cases, **fluorescent in situ hybridization (FISH) analysis is performed with a probe, which contains the gene itself or a nearby gene to detect the missing gene** (Fig. 4-26). A number of microdeletions of specific chromosome regions have been described in association with several specific syndromes (Table 4-1). These syndromes can now be diagnosed by FISH analysis with commercially available DNA probes, standardized

and FDA approved for such purposes (Fig. 4-27).

P.105

Structural Chromosome Alterations

There are two major types of structural alterations, which can occur in chromosomes as a result of a breakage event: (1) that which involves **rearrangement within one chromosome** and (2) that which results from breakage and reunion events in **two or more chromosomes** (Miles, 1961; Daniel, 1988; Borgaonkar, 1989; Edlin, 1990). Unlike nondisjunction events, which result in loss or gain of select chromosomes, breakage can occur anywhere within a chromosome resulting in an unlimited number of rearrangements. Such events usually result in

an unbalanced genetic complement, with some events more lethal than others. Breakage can either occur spontaneously or it can be induced by a mutagenic agent.

Breakage within a single chromosome can result in **duplications, deletions, inversions, isochromosomes, and ring formation**. In each case, the **breakpoint region** is the location of a break in a chromatid or a chromosome and is defined by the exact band involved. A **duplication** is a result of unequal crossing over or unequal sister chromatid exchange, which leads to duplication of a specific chromosome segment, oftentimes in association with deletion of another segment. A **deletion** is the loss of a chromosome segment where a break has occurred either within the chromosome arm (interstitial deletion) or at the end of the chromosome arm (terminal deletion).

An **inversion** results from two breaks occurring within the same chromosome. The segment between the breakpoint regions rotates 180°, and the broken ends fuse together. For example, a chromosome with the sequence ABCDEF, if broken between B and C and between D and E, becomes ABDCEF after the inversion. Inversions may originate from either chromatid or chromosomal breaks. There are two types of inversions, **paracentric** where breaks occur on the same arm on one side of the centromere, in contrast with a **pericentric** inversion in which the breaks occur on both sides of the centromere. In a paracentric inversion, the intra-arm exchange may lead to no apparent altered morphology. In a pericentric inversion, if the breaks are equidistant from the centromere, no apparent change in morphology may occur; but when they are not of equal distance, an abnormal chromosome will result.

An **isochromosome** is a symmetric chromosome composed of duplicated long or short arms formed after misdivision of the centromere in a transverse plane. A **ring** chromosome is formed when breakage occurs simultaneously at two different points on the same chromosome. The resulting “sticky” ends then become rejoined together to form the ring. As a result of the formation of either an isochromosome or a ring, there usually is a significant loss of genetic material along with an associated abnormal clinical phenotype.

Rearrangements that involve more than one chromosome result in the occurrence of dicentrics, insertions, and translocations. A **dicentric** is a chromosome, which has **two centromeres** and is formed by breakage and reunion of two chromosomes. An **insertion** results from transfer of one chromosome's segment into another chromosome. This event involves two breaks in each of the involved chromosomes, and a segment of one chromosome is inserted into the site of breakage in the other.

A **translocation** occurs as a result of breakage followed by **transfer of chromosome material between the involved chromosomes**. There are two types of translocations: **reciprocal**, where there is an **even exchange of material between two different chromosomes**, and **Robertsonian**, when two acrocentrics fuse in the centromere region to **form a single chromosome**. Translocations and other chromosome alterations have a significant effect on the ability of the cell to undergo error-free cell division. Rearranged chromosome material, in the form of a translocation or inversion, will increase the likelihood of acquiring an unbalanced gamete. During the cell division process of translocation chromosomes, loops are formed by homologous segments resulting in partial monosomy or trisomy for the involved regions. In addition, studies of patients with **mental retardation** show an increased frequency of **reciprocal chromosome translocations**. These findings show that there is an increased potential for loss or gain of genetic material, which would ultimately show a phenotypically detrimental effect, usually in the form of mental/growth retardation of the

offspring. Similar observations have not been reported for Robertsonian translocations.

CHROMOSOMES AND HUMAN CANCER

Cancer is a genetic disease of cells caused by DNA damage, often occurring after exposure to an environmental trauma. Such damage is expressed as perturbations in the expression of genes, which control a variety of cellular processes. Cytogenetic analyses demonstrated that some tumor types might have well-defined chromosome changes. Consistency of such changes in association with clinical data may provide diagnostic and prognostic information regarding the tumors' developmental stage and the potential for progression. Detection of a specific chromosome alteration prior to, during, and subsequent to chemotherapy or radiation treatment, is a quantitative measurement, which has been successfully used to determine the efficacy of a specific therapeutic regimen in some malignant diseases. The breakpoint regions involved in consistent cancer-related chromosome alterations have provided important clues as to where the **cancer-associated genes** are located, and the **nature of their protein products**. Drugs, specifically directed at these products, have now been developed.

The most accurate genetic information pertains to leukemias, lymphomas, related hematologic disorders, and some tumors of childhood. For most solid human cancers, including nearly all carcinomas, the information on the sequence of genetic events leading from precancerous lesions to invasive cancer is still fragmentary. The proposed sequence of genetic events in progression of colonic polyps to carcinomas is discussed in Chapter 7. There is hope that the determination of the human genetic code, discussed in Chapter 3 and the

P.106

opening pages of this chapter, may lead to further progress, but it is likely that the road will be long and tedious.

Chromosomal Changes

Primary Chromosomal Changes

First recognized by Nowell and Hungerford (1960), the most consistent primary chromosomal change in human neoplasia is the **Philadelphia chromosome (Ph +)**, which is diagnostic of chronic myelogenous leukemia (CML) (Fig. 4-28). This is a translocation in which a segment of the long arm of chromosome 22 is attached to the long arm of chromosome 9 (Nowell and Hungerford, 1960; Rowley, 1973; Groffen et al, 1984). This rearrangement or **translocation** is an excellent example of a chromosome alteration that characterizes a specific disease and which has been explored at the molecular level and has led to a remarkable development of an anticancer drug (see below). With advances in chromosomal banding techniques, it became possible to identify not only the exact chromosomes involved in the karyotypic changes but also subchromosomal segments.

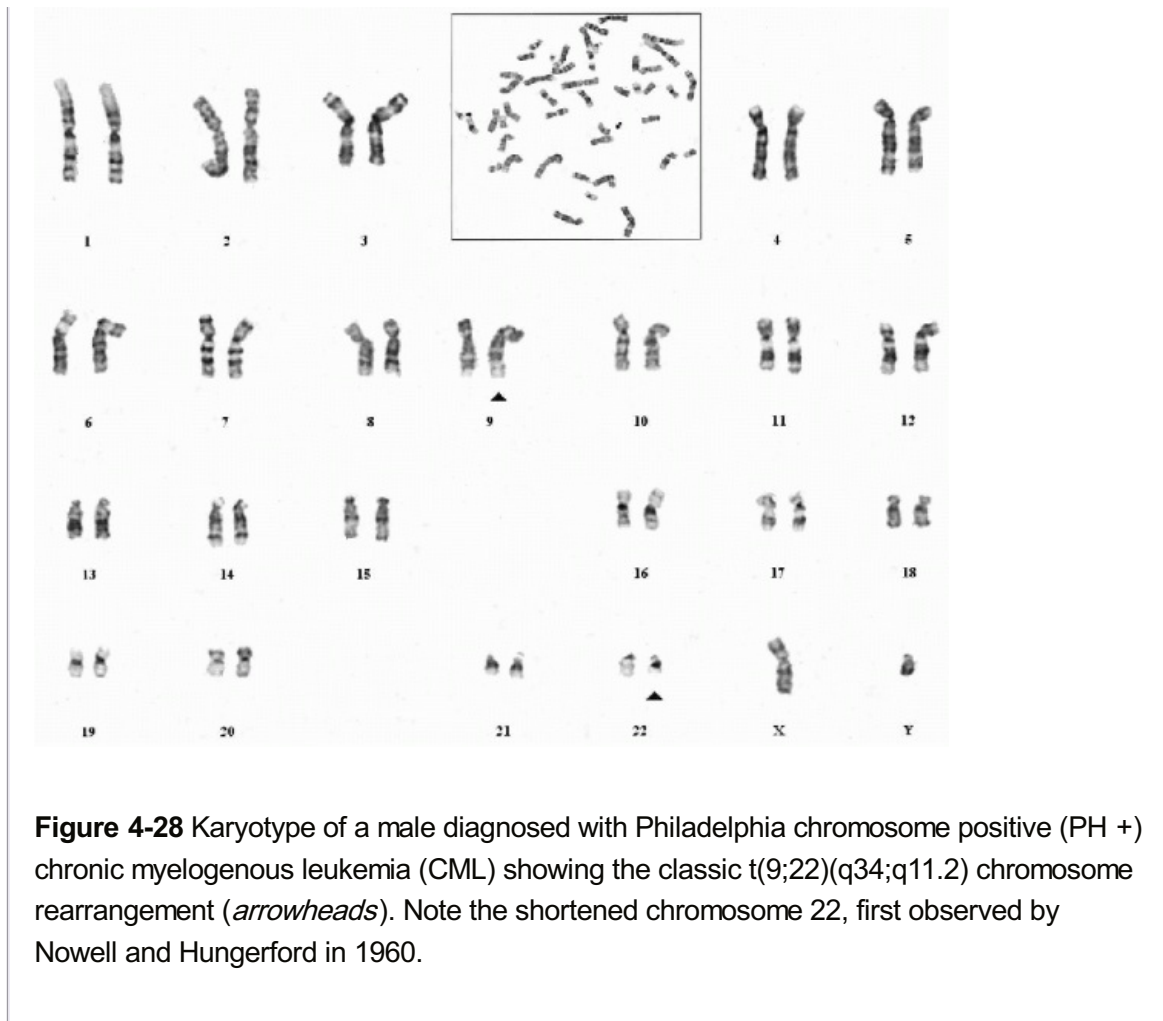

Figure 4-28 Karyotype of a male diagnosed with Philadelphia chromosome positive (PH +) chronic myelogenous leukemia (CML) showing the classic t(9;22)(q34;q11.2) chromosome rearrangement (*arrowheads*). Note the shortened chromosome 22, first observed by Nowell and Hungerford in 1960.

When leukemia or a solid tumor is consistently characterized by one karyotypic anomaly, be it numerical or morphologic, this is considered **a primary or specific cytogenetic event characterizing this disease**. Unfortunately, in common solid tumors, particularly carcinomas, it is very rare to observe a single cytogenetic event. Hence, a series of such tumors must be studied to ascertain whether a change recurs with sufficient frequency to qualify as the primary event. This technique has been used in formulating the possible sequence of events in colonic cancer (Vogelstein and Kinzer, 1998; also see Chapter 7). For most human carcinomas, such a recurrent change has not been convincingly established. It is possible that the primary event in these tumors is submicroscopic, requiring molecular approaches to determine its nature.

Is the primary cytogenetic change causally related to neoplasia? In Ph-positive CML and in some lymphomas, the answer appears to be in the affirmative. In some types of leukemia, there is suggestive evidence that the primary chromosomal abnormalities are the first event leading to the onset of disease. In these conditions, known genes are modified in their structure or activity, with resulting formation of

P.107

abnormal gene products (Knudson, 1986). The reorientation of genes from differing chromosome regions most often results in an **abnormal fusion product**. For example, the abnormality of the **bcr-abl** oncogene may be **the first** manifestation of chronic myelogenous leukemia (see below) whereas, in Burkitt's lymphoma, **a translocation of segments between chromosomes 8 and 14 results in activation of the *myc* oncogene** (Sheer, 1997) (see also below).

Still, the possibility exists that the primary karyotypic change reflects prior events at the molecular level, necessary for the specific chromosomal change to occur (Cannizzaro, 1991; Cahill, 1999). In most leukemias and lymphomas in which the primary chromosomal change has been established, the underlying molecular events have not yet been demonstrated because the abnormalities usually involve large segments of DNA that contain numerous genes. The identification of single genes is not possible until appropriate molecular probes become available. This problem is even greater in conditions in which entire chromosomes are involved, for example, an extra chromosome 8 in leukemia, an extra chromosome 7 in bladder cancer, or a missing chromosome 7 in secondary leukemia. Thus, the deciphering of the molecular basis of most leukemias, lymphomas, or solid tumors is still far off, even if the primary karyotypic change is known. At the same time, it must be stressed that the primary chromosomal change can serve as an important guide to the gene(s) involved. For this reason, it is crucial to rigorously establish the primary changes in as many tumors as possible.

The presence of primary chromosomal changes in **benign tumors** does not indicate that a malignant transformation will occur. This is true whether the primary changes consist of translocations (e.g., **t[3;12] in lipomas** or **t[12;14] in uterine leiomyomas**), deletions (e.g., **22q-** in **meningioma**), or **loss or gain of entire chromosomes** (e.g., **+ 8 in benign salivary gland tumors**). This suggests that the **primary chromosomal changes in benign tumors probably involve genes that are concerned with cellular proliferation but not with malignant transformation**. This may also apply to the secondary chromosomal changes, which may be quite complex in these tumors. Much remains to be established, particularly at the molecular level, in the genetics of benign tumors. Such information should go a long way toward increasing our understanding of the consequence of chromosomal abnormalities in various conditions.

Primary chromosomal changes have been determined in some carcinomas (e.g., 3p in **small-cell lung cancer** and in **renal adenocarcinoma**) (Kovacs et al, 1987; Sandberg, 1990; Heim and Mitelman, 1995). For most carcinomas, however, the primary chromosomal changes have not been established as yet. Because these tumors are characterized by numerous and complex chromosomal changes it is possible that the primary event is masked. The other strong possibility is that these tumors are associated with gene changes at the molecular level that are not discernible with currently used techniques (Mark, 1977; Sandberg, 1985; Mark and Dahlenfors, 1986; Sandberg, 1987; Heim and Mitelman, 1995; LeBeau and Rowley, 1995; Sheer, 1997; Vogelstein and Kinzler, 1998; Meltzer and Trent, 1998).

Secondary Chromosomal Changes

With the passage of time and the evolution of a malignant tumor, whether leukemia or solid cancer, secondary chromosomal abnormalities are often observed. In solid tumors, such changes are often complex and numerous. Except for known secondary changes occurring in some leukemias, such as **i(17)q** in chronic myelogenous leukemia (CML); **+ 8** in acute leukemia (AL); **- Y** or **- X** in acute myelogenous leukemia (AML) with **t(8;21)**, the **secondary chromosomal changes apparently follow a random pattern and invariably appear to be associated with the progression of disease** (Sandberg, 1986; Sandberg, 1990; Harrison et al, 1999). In other words, a leukemia or a solid tumor is at its lowest level of aggressive behavior when it is associated only with the primary karyotypic change. More aggressive behavior is associated with the acquisition of additional chromosomal abnormalities.

What is particularly challenging is the **wide range of secondary changes** that may be present

in a tumor. In **extreme cases, the chromosome count can range from hypodiploidy to hypertetraploidy, and the karyotypes are different for each cell throughout this range.**

A rough idea of these abnormalities may be gained by measuring the DNA content of the tumor cell by image analysis or flow cytometry (see Chaps. 46 and 47). It is likely that the secondary chromosomal changes play a crucial role in the biology of a tumor, that is, invasiveness, metastatic spread, and drug responsiveness. The therapy-resistant cells may ultimately emerge as the dominant cell line in the tumor or leukemia. Thus, in designing successful therapy for various malignant conditions, the presence of additional complex chromosomal changes and their biologic consequences remains an important and difficult obstacle. Cytogeneticists and molecular biologists will ultimately have to come to grips with the nature, significance, and mechanisms responsible for these secondary changes. For example, in carcinomas of the breast, lung, colon, and prostate, the nature and significance of the secondary changes must be elucidated if progress is to be made in the control and cure of these cancers. For comments on specific cytogenetic abnormalities in various solid tumors, see specific chapters. There is some hope that the use of **microarray technology** will facilitate this investigation (Marx, 2000; also see below).

Leukemias

Because culturing lymphoblasts in vitro is easy, consistent chromosome changes have been found in association with specific types and developmental stages of leukemias and lymphomas. The appearance of a specific chromosome alteration, whether it is a **translocation, deletion, inversion, or amplification**, provides clues as to which genes are responsible for the pathogenesis and progression of the disease. This information has facilitated the production of **DNA probes** able to detect disease-specific alterations in both interphase and metaphase stages. Such probes are now being used routinely to provide an accurate diagnosis of a defined malignant condition and to establish which therapeutic regimens are the most effective.

P.108

Cytogenetics has made a greater impact on the diagnostic and clinical aspects of leukemias than on any other groups of diseases. Thus, it has been shown that acute leukemias, which in the past were thought to be a homogeneous group by criteria established by a French-American-British (FAB) consensus agreement that relied heavily on cellular morphology and immunology and, in fact, consisted of a **number of subgroups**, each characterized by a specific cytogenetic change (Tables 4-2 and 4-3).

As aforementioned, chronic myelogenous leukemia (CML) was the first disease to be characterized by a specific chromosomal change, the Philadelphia (Ph) chromosome. The Ph chromosome is diagnostic of the disease, although it may also be seen in some acute lymphocytic leukemia (ALL) and acute nonlymphocytic leukemia (ANLL) cases. The translocation breakpoint of the 9;22 rearrangement, which generates the Ph chromosome differs in CML and ALL, and involves different sequences at the molecular level for each of these diseases (Cannizzaro et al, 1985).

The appearance of secondary chromosomal changes in Ph-positive CML usually consist of additional Ph chromosomes; an i(17q), + 8, or + 19, heralds the onset of the blastic phase of this disease before clinical evidence is apparent. It is quite likely that additional variants of leukemias will be defined cytogenetically. Each year, a few new subentities are reported and additional classification of leukemias based on molecular analysis is probable.

Prognosis, Treatment, and Follow-Up

The cytogenetic findings in acute leukemias are an independent prognostic factor. Primary chromosomal changes appear to decide the behavior and prognosis. Additional quantitative and qualitative chromosomal changes are also of prognostic significance. The additional secondary karyotypic changes modify the prognosis, usually for the worse. Generally, the presence of cytogenetically normal cells improves the prognosis of acute leukemia and related disorders, such as myelodysplasia; the absence of normal cells worsens it. Also, the increasing complexity of the karyotypic picture (**major karyotypic abnormalities [MAKA] versus minor karyotypic abnormalities [MIKA]**) increases the chances of a poor prognosis.

Cytogenetic analysis of bone marrow cells is an essential part of follow-up in acute leukemias. Thus, the presence of only a rare cell, with a primary chromosomal change demonstrated at the time of the original diagnosis, indicates

P.109

that a remission is not complete or that imminent relapse is likely to occur.

 LeBeau MM, Rowley JD. Cytogenetics. In: Hematology, 5th ed. Beutler E, Lichtman MA, Coller B, Kipps TJ, eds. McGraw Hill, NY, 1995, pp 98-106.

Molecular cytogenetics has now contributed to the therapy of chronic myelogenous leukemia. As has been discussed above, the principal abnormality, resulting in a Ph chromosome, is a translocation of segments of chromosomes 9 and 22. The product of this translocation is a protein known as **bcr-abl-tyrosine kinase**. Recently, an inhibitor of this kinase (Gleevec) has been developed and put to clinical use in treatment of chronic myelogenous leukemia with remarkable results (Druker et al, 2001a, 2001b; Mauro and Druker, 2001). Some patients responded to the drug with return to normal blood count and disappearance of the leukemic process. The longterm effects of this drug are still unknown at the time of this writing (2004). Interestingly, the drug also appears to be effective in **gastrointestinal stromal tumors** (Joensuu et al, 2001) although these tumors do not express bcr-abl-tyrosine kinase (see Chap. 24).

It is now clear that the chromosomal changes in leukemia can be of critical value in the treatment of these diseases. With the accumulation of appropriate data suitable for analysis in other conditions, such as solid tumors, it is possible that the cytogenetic findings will provide another prognostic parameter in addition to the customary assessment of tumor grade and stage.

P.110

Bone Marrow Transplantation

Cytogenetic studies in bone marrow transplantation (BMT) can determine whether the cells in the bone marrow are of donor or host origin. This can be accomplished when the leukemic cells are characterized by a specific anomaly or when the sex of the donor and host differ. The finding of even an occasional abnormal cell following BMT strongly suggests that leukemic cells are still present in the host's marrow. **FISH analysis with DNA probes specific for an altered chromosome region or for a sex chromosome**, has proved valuable in rapid and accurate determination of the presence or absence of donor cells in BMT patients (Garcia-Isodoro et al, 1997; Tanaka et al, 1997; Korblyng, 2002).

Lymphomas

The definition of karyotypic abnormalities in Burkitt's lymphoma (BL) in cytogenetic terms is a translocation between segments of chromosomes 8 and 14, that is, [t(8;14)(q23; q32)] is one of the milestones in cancer cytogenetics. The demonstration that some BL cases have variant translocations [e.g., t(2;8)(p12;q24) or t(8;22)(q24;q11)] is an example of the cytogenetic characterization of subtypes of this tumor (Zech et al, 1976). The **identification of the molecular events** associated with the cytogenetic changes in BL pertaining to various **immunoglobulin genes** and the **oncogene c-myc** constitutes one of the exciting developments in human neoplasia.

Subsequent to the description of chromosomal changes in BL, several specific changes were established for other types of lymphoma (see Table 4-3), of T-cell or B-cell origin. These changes were then correlated with corresponding molecular events, such as the changes in the various T-cell receptors and **bcl** genes. The chromosomal changes described in lymphomas have been correlated with their histology and immunophenotype, as well as with prognosis. Although progress in the cytogenetic aspects of lymphomas has not been as decisive as in leukemias (particularly of the acute variety), the introduction of a universally acceptable classification system of lymphomas by WHO contributed to a meaningful correlation with cytogenetic findings (see Chap. 31).

Solid Tumors

Hematopoietic neoplasms account for fewer than 10% of human cancers; the remaining cancers are solid tumors. Unfortunately, because of the difficulty in culturing in vitro, the cytogenetic analysis of solid tumors has not kept pace with cytogenetics of leukemias and lymphomas. Further, the presence of multiple clonal abnormalities in many solid tumors, observed in later developmental stages, makes it difficult to ascertain which chromosome alterations are responsible for the tumor's pathogenesis. Improvements in short-term culture techniques and chromosome banding methods, in conjunction with earlier diagnosis of tumors, have helped to overcome some of these difficulties.

Consistent chromosome alterations, which possibly represent primary changes of specific

genome regions, have now been identified in some carcinomas, such as **breast, lung, kidney, prostate, and colon** (Table 4-4) (First International Workshop on Chromosomes in Solid Tumors, 1986; Second International Workshop on Chromosomes in Solid Tumors, 1987; Sandberg, 1990; Heim and Mitelman, 1995; Sheer, 1997; Meltzer and Trent, 1998). Such regions have been found to contain either **a tumor-suppressor gene or an oncogene**, which are believed to be involved in either the pathogenesis or progression of the tumor to malignant transformation. It has been shown in various tumors that the number of chromosome alterations reflects the number of mutations occurring at the molecular level. As the number of chromosome alterations increases, so does the malignant potential of the tumor, ultimately evolving into a disease less likely to have a good prognosis.

Advances in methodology have made possible the detailed examination of the karyotypes of several tumor types, such as some sarcomas, testicular and kidney cancers, and neuroblastoma (Sandberg, 1985, 1990). These advances have led to the description of a number of specific chromosomal changes in solid tumors, which have opened the door to more detailed molecular definition of the genes involved in the tumors' behavior and progression. As in leukemias, the combination of cytogenetic and molecular analysis is likely to lead to a definition of subtypes within existing tumor groups. These may influence the diagnosis, classification, development of therapeutic approaches, and prognostic aspects of these tumors. An example of the impact of genetics on solid tumors is the discovery of breast cancer genes 1 and 2 (BRCA1 and BRCA2) that, if mutated, put a woman at risk for the development of breast or ovarian cancer (Vogelstein and Kingler, 1998; also see Chaps. 16 and 29). Still further advances may be expected with molecular classification of disease processes or **genomics** (Golub et al, 1999; Dohner et al, 2000; Guttmacher and Collins, 2002).

Normal Karyotypes in Cancer

The presence of **normal diploid karyotypes** in preparations from leukemic cells or solid tumors has generally been assumed to be due to the presence of normal cells, although it cannot be ruled out with certainty that such cells are not cancerous or leukemic and may, in fact, have a submicroscopic genetic change not discernible with cytogenetic techniques. The normal cells in such preparations as bone marrow in leukemia may be of normoblastic, fibroblastic, or uninvolved leukocytic origin. In solid tumors, a similar situation may be encountered and, in all probability, the diploid cells are of fibroblastic (or other stromal cell) and/or leukocytic origin.

There is no doubt, however, that many cancer cells have a diploid DNA content, measured by flow cytometry and image analysis of cancer of the breast and other organs (summary in Koss et al, 1989; see also Chaps. 46 and 47).

At the molecular level, it is possible that a diploid cell is altered in some way. Such submicroscopic alterations can be detected by molecular techniques and are usually defined as **loss of heterozygosity (LOH)**. LOH involves the removal or inactivation of a tumor suppressor gene and it can be brought about by various mechanisms (Knudson, 1986; Lewin, 1997).

P.111

To document LOH, the tumor DNA is cut into segments of varying length by an endonuclease (see Chap. 3). The resulting DNA fragments are separated by gel electrophoresis, and the segment with a selected gene is marked by binding a labeled cDNA. Because of individual variability, the two DNA fragments containing the genes that are derived from maternal and

paternal chromosomes will be of different lengths and will appear as two bands on the gel. If one gene is mutant and, therefore, fails to bind the cDNA, there will be only one band (hence, loss of heterogeneity; LOH).

TABLE 4-4 RECURRING CHROMOSOME ABNORMALITIES IN HUMAN SOLID TUMORS

Tumor Type	Primary Karyotype Abnormalities
Bladder	+7; del(10)(q22-q24); del(21)(q22)

ADVANCES IN GENETIC DIAGNOSTIC TECHNIQUES

The use of higher-resolution molecular cytogenetic techniques, such as **fluorescent in situ hybridization (FISH)** and **multicolor hybridization analysis (M-FISH/SKY)**, have contributed enormously to the advancement of knowledge about the regions of the genome that are involved in the development and progression of genetic and malignant diseases. These techniques utilize **DNA probes and libraries to identify and position DNA sequences along the length of a chromosome** and require actively dividing cells. On the other hand, techniques such as **comparative genomic hybridization (CGH)** and **DNA hybridization arrays** require only DNA or RNA of the target cells or tissues and do not depend on cell division. Each of these techniques is discussed in further detail below.

Fluorescent In Situ Hybridization

Fluorescent in situ hybridization (FISH) is a molecular cytogenetic technique, which permits **direct visualization of a DNA sequence on a specific chromosome site**. DNA sequences ranging in size from <1 kb to several hundred megabases can be rapidly and accurately positioned at a specific chromosome site. The DNA probe is first labeled with an immunofluorescent compound such as biotin-11-dUTP or digoxigenin-11-dUTP, and is then **hybridized overnight either to metaphase chromosome or interphase preparations**. The resultant fluorescent signal where homologous sequences have joined together is detected under ultraviolet light with filters capable of resolving wavelengths specific to the fluorescent compound (Fox et al, 1995).

This technology has facilitated **the construction of a**

P.112

physical map of genome regions, which play a critical role in genetic or malignant disorders. As mentioned above, DNA probes are now commercially available and are designed to detect microdeletions such as the absence of the elastin (ELN) gene at chromosome region 7q11, associated with the appearance of **Williams syndrome**. Deletion of the ELN gene is not detectable by either standard- or high-resolution cytogenetic analysis, but is easily detected

with fluorescent in situ hybridization. Commercial probes can detect the sequences that would be lost if the microdeletion event occurred, in addition to containing a probe, which would identify the chromosome itself, in this case a chromosome 7-specific sequence (see Fig. 4-26).

In addition to sequence-specific probes, probes have been constructed that are able to identify **whole chromosomes or chromosome arms**. Such “**painting**” probes are generated, either by flow sorting of select chromosomes or by microdissecting chromosome bands directly from a metaphase preparation. Painting probes have been used to identify and define **structural and numerical alterations of chromosomes in the metaphase and in the interphase stage** (see Fig. 2-31) (Ried et al, 1998; Koss, 1998; Ludecke et al, 1989).

Spectral Karyotyping and Multicolor FISH

Spectral karyotyping (SKY) and multicolor FISH (M-FISH) are adaptations of the FISH technology and are being used to identify unusual structural and numerical chromosome alterations, particularly in neoplastic diseases. This technology uses a combination of specialized filters along with at least five different immunofluorescent compounds that are combined in different proportions to produce a range of different colors, so that a specific color precisely and consistently identifies each chromosome. Multicolor/spectral karyotyping makes it possible to identify the origin of chromosome material, which produces a marker chromosome arising from a rearrangement of sequences from two or more differing chromosomes (Ried et al, 1997; Veldman et al, 1997; Chudoba et al, 1999; Hilgenfeld et al, 1999; Ning et al, 1999).

Figure 4-29 The Philadelphia chromosome results from a translocation $t(9;22)(q34;q11.2)$ which fuses the *c-abl* proto-oncogene on chromosome 9 to the *bcr* (breakpoint cluster region) on chromosome 22. A probe detects the *bcr/abl* gene fusion (Philadelphia chromosome) in interphase cells. The *bcr* sequences are directly labeled with SpectrumGreen fluorophore and the *abl* sequences are directly labeled with SpectrumOrange fluorophore. Separated green and red signals indicate unrearranged chromosomes 22 and 9 respectively, while yellow signal indicates fusion of *bcr/abl* sequences. The majority of interphase cells show fusion signals and confirms diagnosis of

patient with PH + CML.

Chromosome Microdissection

This is another relatively new technique, which helps to define chromosome segments or marker chromosomes that are not identifiable by conventional cytogenetic techniques. A chromosome region of unknown identity is dissected out of a metaphase either manually, using a microdissecting needle, or with a laser. DNA is isolated from the micro dissected fragments, labeled with a fluorescent tag, and a **micro-FISH** probe is constructed. The resulting DNA probe will **hybridize to corresponding sequences on normal chromosomal metaphases** to identify the origin of the unknown segment. This technique has been successfully used to **identify the origin of marker chromosomes** in both genetic and malignant diseases (Ludecke et al, 1989; Cannizzaro, 1996; Cannizzaro, 1997). It has also proved useful in generating DNA probes directly from commonly altered genome regions in an effort to determine how and which genes are repositioned as a result of the alteration.

One of the most important uses of the FISH technology is the determination of a **gene's orientation in relation to another gene or group of genes** after either a translocation or an inversion (Shi and Cannizzaro, 1996; Cheng et al, 2001). A **gene placed in a new position as a result of a chromosome alteration will most likely produce an altered form of the gene product**. For example, as described, a translocation between the long arms of chromosomes 9 and 22, results in producing the **Ph chromosome**, and is diagnostic of chronic myelogenous leukemia (CML) (see Fig. 4-28). This 9;22 translocation results in fusing DNA sequences, **bcr** (breakpoint cluster region) from chromosome 22, and the protooncogene, **abl**, from chromosome 9, and produces an altered gene product (**bcr:abl**). Sequences from the two involved chromosomes are labeled with two different immunofluorescent compounds, one producing a green signal, and the other producing a red signal. Fusion of bcr:abl sequences from the two chromosomes can then be detected as a yellow signal produced by the overlapping red and green signals from each of the

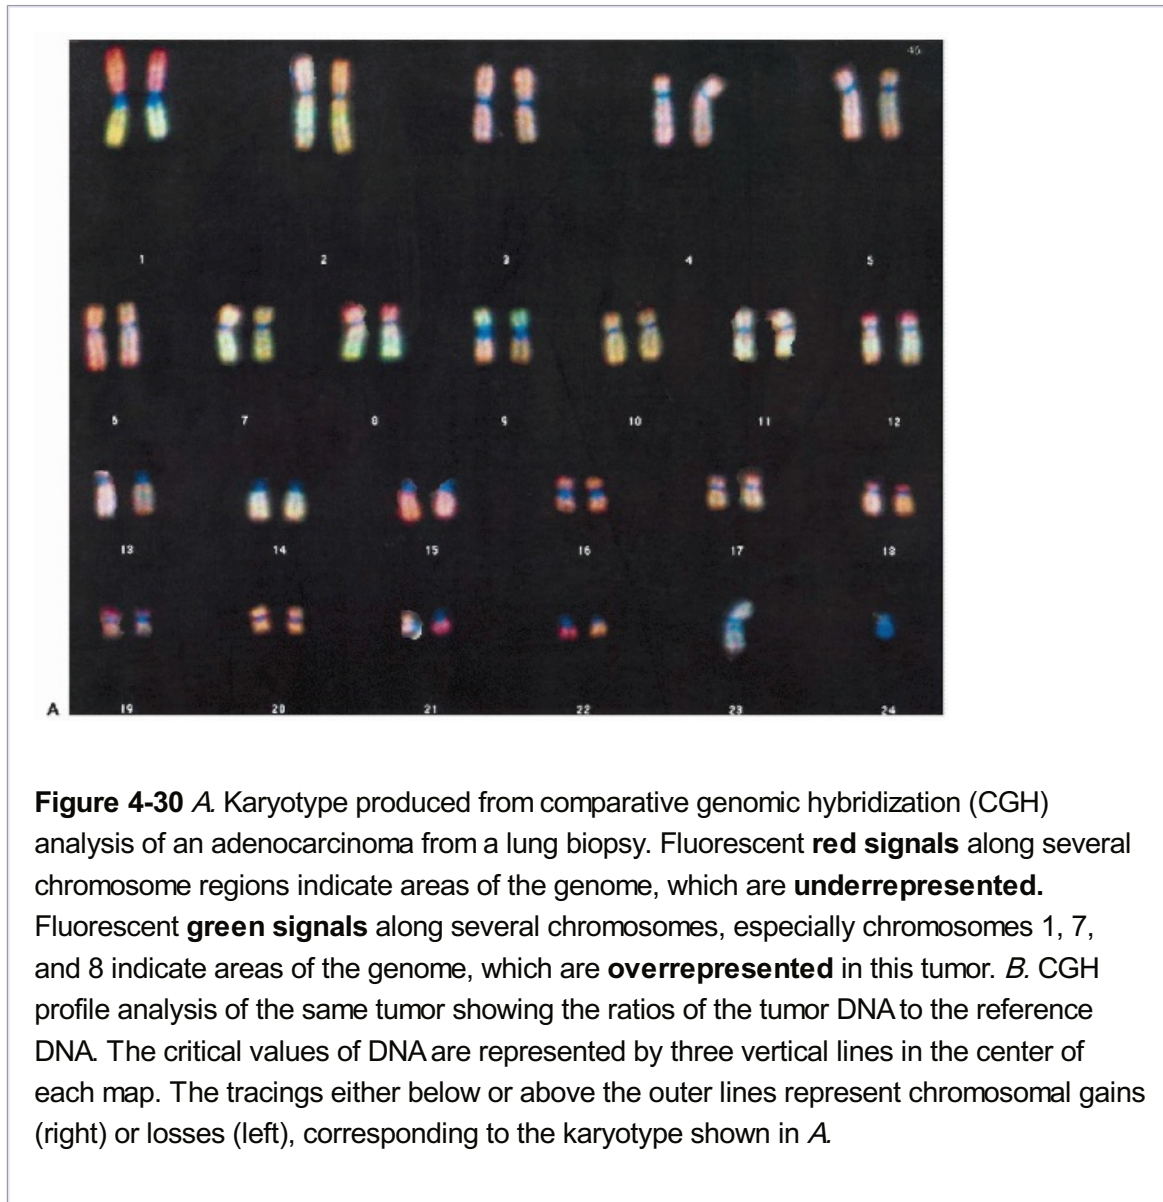

P.113

involved chromosomes (Fig. 4-29). This **translocation event is detectable in the interphase**, permitting a diagnosis even in those cases where the patient's cells are not dividing and, hence, do not form metaphases or have been subjected to chemotherapy or radiation therapy. Similar translocation or fusion products can now be detected and identified for several different malignant events because of consistency of the altered DNA sequences.

Comparative Genomic Hybridization

In recent years, the technique of comparative genomic hybridization (CGH) has been introduced. This technique can generate a genetic profile of a tumor cells' DNA in interphase. The signal advantage of this technique is that it **requires only a small amount of tumor DNA** (2 µg per experiment). The labeled tumor DNA is **hybridized with normal metaphases**, competing with a differently labeled tumor DNA of known makeup. The resulting hybridized metaphases **are analyzed by a computer program that determines gains or losses of individual chromosomes**. CGH studies of a variety of tumors have yielded a significant amount of new information regarding regions of the genome, which contain potential tumor suppressor genes or candidate tumor promoter genes. In many of these tumors, this technology has detected alterations in genome regions that had not been detected previously either by

cytogenetic or molecular analysis (DuManoir et al, 1993; Ried et al, 1997).

Regions of the genome that are either under- or overrepresented in sequence copy number are easily identified as fluorescent red or green regions in comparison with the normal genome (Fig. 4-30). In certain tumors, such as lung, breast, ovary, and prostate, a significant amount of new information has been obtained to identify regions of the genome, which may contain potential oncogene or tumor suppressor loci (Kallioniemi et al, 1992; Houldsworth and Chaganti, 1994; Zitzelsberger et al, 1997).

As an example of this technique, Figure 4-31 shows the results of CGH applied to DNA samples of endometrial glands in atypical hyperplasia and endometrioid carcinoma (Baloglu et al, 2001). Gains in chromosome 1 and gains and losses in chromosomes 8 and 10 were the most frequent genetic abnormalities that were common to both processes, suggesting their similarity or identity (for further comments, see Chap. 14).

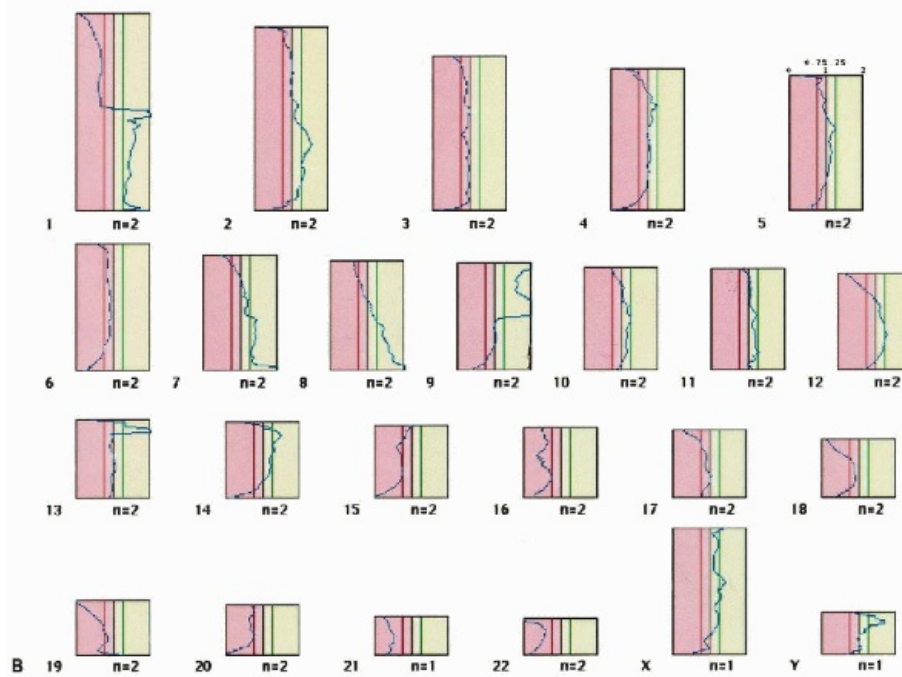

Figure 4-30 (*continued*)

DNA Microarray

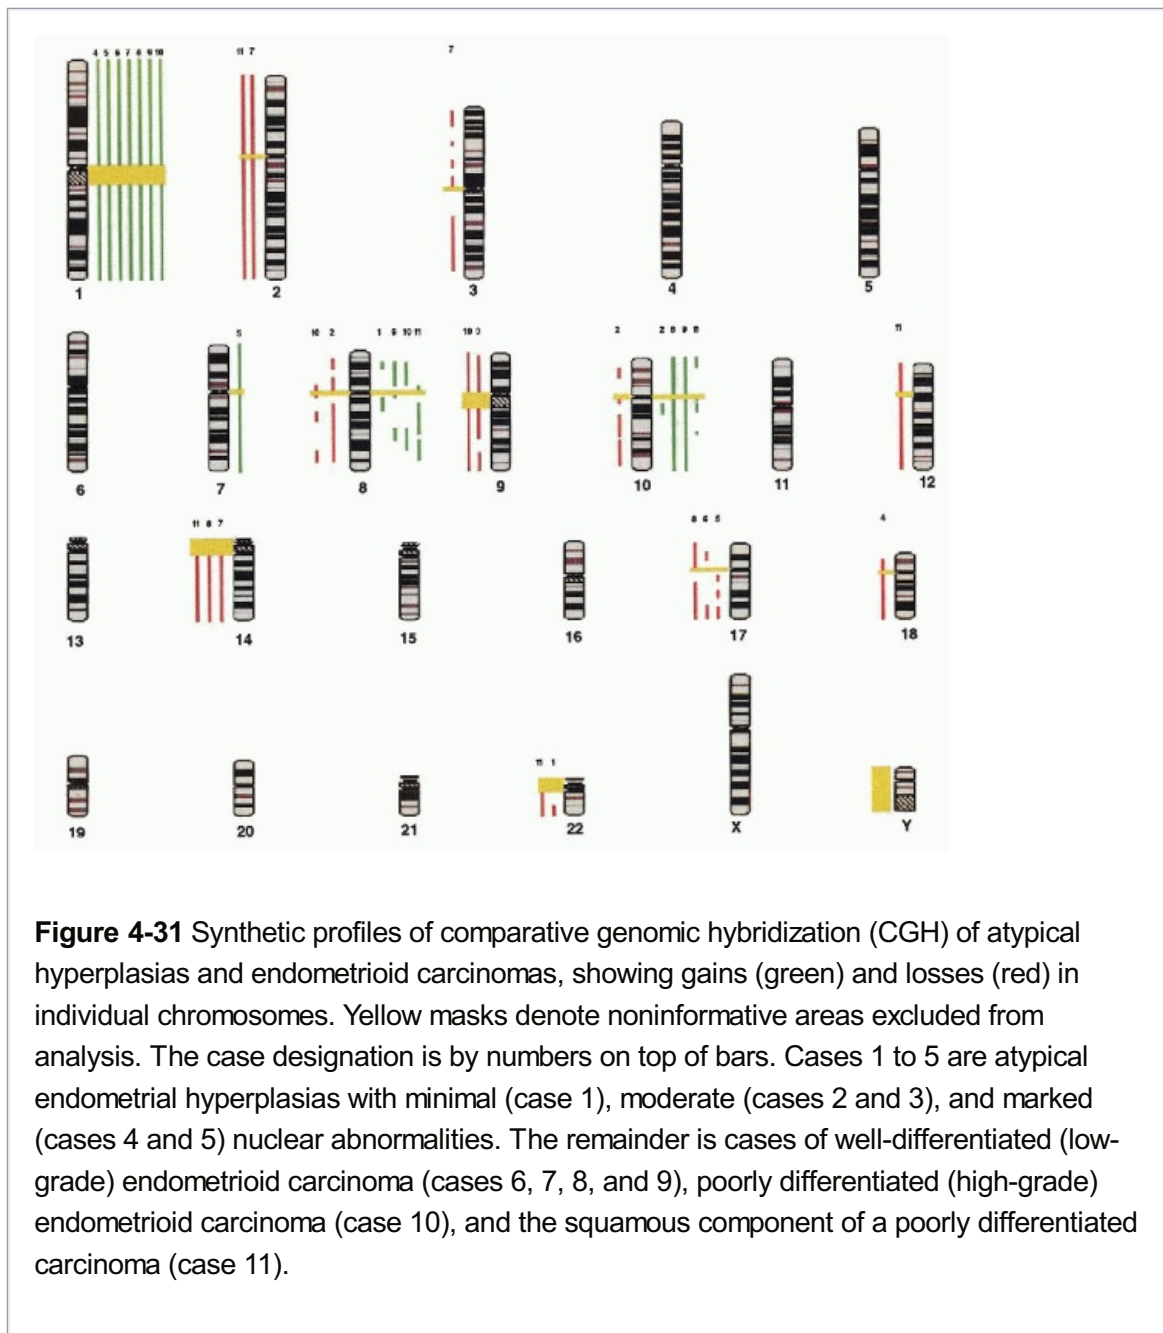

The emergence of a new technology known as **microarray analysis** has caused a surge in new information about which genes are involved in different forms of cancer. Previous to the initiation of the microarray system, each cancer was studied on a gene-by-gene basis, primarily using **Northern blot analysis or reverse transcriptase-PCR (RT-PCR)** analyses to determine the level of expression of a specific gene in a cancer. The microarray technology consists of a **slide or chip dotted with DNA from thousands of genes**, which can serve as probes for detecting which genes may be active in cancer cells from different types and stages of tumors. The **mRNA** is obtained from fresh tumor tissue and serves as a template to create the **corresponding cDNA**. The cDNA from cancer cells is given a red fluorescent label, while those from normal cells get a green label. Equal amounts of the two cDNAs are applied to the array; a red signal indicates higher expression of the gene in cancer cells, a green signal indicates higher expression of the gene in normal cells, while a yellow signal indicates an equal expression of that gene in both normal and cancer cells (Fig. 4-32). As a result, it is now possible to determine the level of expression of an enormous number of genes corresponding to a particular type and stage of cancer (Schena et al, 1995; DeRisi et al, 1996; Shalon et al, 1996; Brown and Botstein, 1999; Freeman et al, 2000; Rosenwald et al, 2002; summary in Macosca, 2002).

The microarray analyses have been performed on some leukemias and some solid tumors. Preliminary studies of a series of patients with either AML or ALL show two distinct patterns of gene expression (Golub et al, 1999). Similar results were obtained in a subsequent study of patients with diffuse large-cell lymphoma, a common type of non-Hodgkin's lymphoma. In a study of 40 patients, the microarray gene expression profiles indicated the patients could be divided into two groups, with one group expressing genes turned on in B cells in the spleen and lymph nodes during an immune response, while the other group did not express these genes,

but expressed a set of genes, which are stimulated to divide an antigen. The expression profiles also correlated well with prognosis of the two groups of patients, with the first group faring better than the second (Freeman et al, 2000). A recent study of breast cancer occurring in patients with either BCG1 or BCG2 mutations suggested some differences between these two groups of tumors do occur but their significance is unknown (Hedenfalk et al, 2001).

Microarray analyses are becoming an important tool to sort out the differences in different types and stages of cancer; however, the **interpretation of findings is extremely difficult**. It is hoped that ultimately this information will help in the development of new drugs designed to influence specific target cells and, thus, will enhance the effectiveness of a therapeutic regimen.

P.115

P.116

Figure 4-32 cDNA microarray analysis of squamous cell carcinoma of the head and neck region (HNSCC). RNA from HNSCC was compared to RNA from normal, adjacent epithelium. The array contains 27,323 cDNA clones. Red spots = overexpression in HNSCC; green spots = underexpression in HNSCC; yellow spots = equal expression in HNSCC and normal tissue; black = no expression in either sample. The interpretation of microarray results is difficult and time-consuming. (Courtesy of Drs. Thomas J. Belbin, Michael B. Prystowsky, and Geoffrey Childs, Albert Einstein College of Medicine and Montefiore Medical Center, Bronx, NY.)

Appendix

GLOSSARY OF CYTOGENETIC TERMS

p:

short arm of a chromosome (from French, *petit*)

q:

long arm of a chromosome (letter following p)

+: (plus sign):

added chromosome (+ 8) or chromosomal segment (8q+)

-: (minus sign):

lost (deleted) chromosome (-7) or chromosomal segment (5q-)

t:

translocation (exchange) between chromosomes and chromosomal segments

Example: t(9;11) (q31;q21.1) = translocation involving breaks at band q31 on chromosome 9 and band q21.1 on chromosome 11

del:

deletion, followed by chromosome number, arm (short = p, long = q) and, if known, band number.

Example: del(13q14) = deletion from chromosome 13 of band 14 located on the long arm of the chromosome (location of retinoblastoma gene)

i:

isochromosome, followed by chromosome number and arm.

Example: i(5p), duplication of short arm of chromosome 5 (change observed in bladder cancer)

inv:

inversion, upside-down position of a segment of a chromosome

5

Recognizing and Classifying Cells

Light microscopic examination of stained cells in smears is the method of choice of diagnostic cytology. It allows classification of most normal cells as to type and tissue of origin. It also allows the recognition of cell changes caused by disease processes, discussed in general terms in Chapters 6 and 7 and, more specifically, in subsequent chapters.

GENERAL GUIDELINES

The study of cells in smears should take place at several levels:

- A rapid review of the smear with a 10× objective provides information on the makeup of the sample and its cell content. This preliminary review will tell the observer whether the smear is appropriately fixed and stained and will provide initial information on its composition. Smears containing only blood or no cells at all are usually considered inadequate, with some very rare exceptions.
- If the smear contains cells other than blood cells, it should be examined with care. A careful review of the material or **screening of smears** with a 10× objective is usually required to identify abnormal cells that may be few in number. Screening is **mandatory** in cancer detection samples from “well” patients. A microscope stage should be utilized. The methods of screening are described in Chapter 44.
- The screening of the smear should lead to the **preliminary assessment of the sample** and answer the following questions: (1) Does the cell population correspond to the organ of origin? (2) If the answer is positive, the next question pertains to the status of the cell population: (a) is it normal? (b) does it show nonspecific abnormalities of little consequence to the patient? or (c) Does it show abnormalities pertaining to a recognizable disease state that can be identified?

To answer these questions, fundamental principles of cell classification must be presented.

CELL CLASSIFICATION

An Overview of the Problem

In general, **the derivation, type of cells, and sometimes their function, are reflected in the cytoplasm**, whereas the **nucleus offers information on the status of the DNA**, which is of particular value in the diagnosis of cancer. Some cells that lack distinct cytoplasmic or nuclear features may be very difficult to classify. Nuclear and nucleolar changes in cancer are described in detail in Chapter 7.

Knowledge of the rudiments of histology is necessary for cell classification. For all practical purposes, the **cells encountered in cytologic samples are of epithelial and nonepithelial**

origin. The most common cell types will be discussed here. Other cell types will be described as needed in appropriate chapters.

With the development of **monoclonal or polyclonal antibodies** to specific cell components, still further insights into cell derivation and function can be achieved by

immunocytochemistry. An immunochemical analysis of the **components of the cell skeleton**, such as the intermediate filaments, of **cell products**, such as various hormones, and of immunologic features vested in the cell membrane, allows additional analysis and classification of cells (see Chap. 45).

An additional point must be made in reference to the **comparison of tissue sections and cells** of the same origin.

P.120

In **tissue sections**, the **cells** are often cut "on edge" and are **seen in profiles**. In **cytologic preparations**, the **cells are whole** and are generally flattened on a glass slide, usually affording a much better analysis of the cell components. A schematic comparison of histology and cytology is shown in Figure 5-1. A description of the principal tissue and cell types observed in diagnostic cytology is provided below.

Epithelial Cells

An epithelium (**plural: epithelia**) is a **tissue lining the surfaces of organs or forming glands and gland-like structures**. Similar epithelia may occur in various organs and organ systems. There are four principal groups of epithelia: (1) **squamous epithelia**, synonymous with protective function; (2) **glandular epithelia with secretory functions**; (3) **ciliated epithelia**; and (4) **the mesothelia**.

Squamous Epithelium

Histology

The squamous epithelium is a multilayered epithelium that lines the surfaces of organs that are in direct contact with the external environment. Two **subtypes** of this epithelium can be recognized: the **keratinizing type**, occurring in the **skin** and the **outer surface of the vulva** and the **non-keratinizing type**, occurring in the **buccal cavity, cornea, pharynx, esophagus, vagina and the inner surface of the vulva**, and the **vaginal portio of the cervix**. The differences between the two subtypes of squamous epithelium reside in their mechanisms of maturation and formation of the superficial layers, discussed below.

Squamous epithelium is organized in **multiple layers**. Starting at the bottom of the epithelium, resting on the lamina propria, to the top of the epithelium, facing the surface, four principal layers can be distinguished, although the separation of the layers is arbitrary. The bottom, **basal layer**, is composed of small cells. Immediately above are the **parabasal layers**, composed of two or three layers of somewhat larger cells, which blend with the next **intermediate layers**, composed of several layers of larger cells. The fourth **superficial layers** of the squamous epithelium are composed of a variable number of layers of the largest cells.

Figure 5-1 Comparison of histology and cytology of three common types of epithelia.

A. Squamous epithelium. The cells are provided with a rigid skeleton of intermediate filaments; hence, they are resistant to injury. The cells vary in size and configuration, depending on the layer of origin. Cells from the superficial layer are large, with abundant cytoplasm and small nuclei. Cells from the intermediate and parabasal layers are smaller and have an open, spherical nuclei (vesicular nuclei). Cells from the basal layer are still smaller, but the nuclear structure is identical with that of parabasal cells. **B. Glandular epithelium.** These epithelia are usually quite fragile and are often injured, hence, poorly preserved. The cells may vary in size from cuboidal to columnar. Small contractile myoepithelial cells often accompany glandular cells. **C. Ciliated epithelium with mucus-secreting cells.** The ciliated cells are readily recognized because of the flat, cilia-bearing surface and a thin, taillike opposite end. The mucus-producing cells (goblet cells) are of a similar configuration but have no cilia, and their cytoplasm is distended with mucus-containing vacuoles.

The epidermis of the skin is the prototype of squamous epithelium (Fig. 5-2). The features conferring special **strength** on this epithelium are **keratin filaments of high relative molecular mass**, and numerous **desmosomes**, cell junctions that are very difficult to disrupt (Fig. 5-3; see also Fig. 2-13).

The growth of the squamous epithelium is in the direction of the surface, that is, the **cells move from the basal layer, to parabasal layers, to intermediate layers, to superficial layers**. The most superficial cells are cast off. Under conditions of health, the small **cells of the basal layer** are the only cells in this type of epithelium that are **capable of mitosis**. It should be noted that the **cells of the basal layer have several different functions**: some anchor the epithelium to the basement lamina, some provide new basal cells to ensure the survival of the epithelium, and some produce cells that are destined to mature and thus form the

bulk of the epithelium. **There are no morphologic differences among the basal cells with different functions.**

As the cells transit from the basal to the more superficial layers, they are programmed to **gradually increase the size** of their cytoplasm. The increase in the size of the cytoplasm is accompanied by an increase in the intermediate keratin filaments of high relative molecular weight (see Fig. 2-27). As the cells progress through the stages of maturation, they are bound to each other by desmosomes, until they reach the superficial layer, where the desmosomes disintegrate to allow shedding of the most superficial cells. The process of **cytoplasmic maturation is accompanied by nuclear changes**. The nuclei of the basal, parabasal, and intermediate layers of squamous cells appears as spherical, **open (vesicular)** structures, measuring approximately 8 μm in diameter. As the cells transit from the intermediate to superficial layers, their nuclei **shrink and become condensed (nuclear pyknosis)**.

P.121

Figure 5-2 Histologic section of normal human skin as an example of squamous epithelium with protective function. Note the small cuboidal cells of the basal layer adjacent to connective tissue of the dermis (*bottom*). The surface is formed by several “basketweave” layers of anucleated squames. The bulk of the epithelium is composed of intermediate cells. Scattered cells with clear cytoplasm are the Langerhans' cells, representing the immune system.

Figure 5-3 Electron micrograph of middle layer of human epidermis. The nuclei (N) are surrounded by a perinuclear clear zone free of filaments. The remaining cytoplasm shows an abundance of intermediate filaments forming aggregates (bundles) seen in longitudinal, oblique, or transverse section. Many of the filament bundles terminate on the numerous desmosomes, some identified by arrows. The integrity of the desmosomes accounts for the cohesion of this type of epithelium. ($\times 18,000$.) (Courtesy of the late Dr. Philip Prose, New York University, New York.)

P.122

The differences between the two subtypes of the squamous epithelium are evident in the superficial layers: in the **nonkeratinizing squamous epithelium**, the superficial cells are cast off, **while still retaining their nuclei** (see Chaps. 8 and 19). In the **keratinizing squamous epithelium**, such as the epidermis of the skin, the superficial cells continue to accumulate keratin filaments, which obliterate the nucleus until the cell becomes an anucleated, keratinfilled shell (**anucleated squames**). The anucleated squames of the epidermis form a superficial

horny layer, which provides the best protection against injury (see Fig. 5-2).

Under abnormal circumstances, formation of a horny layer may also occur in nonkeratinizing squamous epithelia, resulting in white patches visible with the naked eye, and, therefore, known as **leukoplakia** (from Latin, *leukos* = white and *plax* = plaque). This condition may occur in the uterine cervix or the buccal cavity and is described in the appropriate chapters.

Squamous epithelia are also provided with cells with **immune function**, the **Langerhans' cells**, characterized by clear, transparent cytoplasm (see Fig. 5-2). These cells appear to mediate a broad variety of immunologic responses of the squamous epithelia to environmental and internal stimuli (summary in Robert and Kupper, 1999).

Cytology

Cells derived from squamous epithelia are usually quite resilient to manipulation and often retain their shape because of high keratin content. In general, these cells tend to be **flat, polygonal, and sharply demarcated**, and they **vary in size according to the layer of origin**. The smallest cells, measuring about 10 μm in diameter, are the **basal cells**, which are very rarely seen in normal states. **Parabasal cells**, derived from the parabasal layers, are somewhat larger, measuring from 10 to 15 μm in diameter. **Intermediate cells**, derived from the intermediate layers, are still larger, measuring from 15 to 40 μm in diameter. The **superficial cells** are the largest, measuring from 40 to 60 μm in diameter. The cells derived from the **basal, parabasal, and intermediate layers** show spherical nuclei, resembling open vesicles, with delicate chromatin, hence the term **vesicular nuclei**, measuring about 8 μm in diameter. The **superficial squamous cells** derived from non-keratinizing squamous epithelium, show small, **condensed, and dark nuclei** that are often encircled by a narrow clear cytoplasmic zone of contraction. Such nuclei are referred to as **pyknotic nuclei** (from Greek, *pyknos* = dense) (Figs. 5-4 and 5-5). **Anucleated squames**, derived from keratinizing squamous epithelium, appear as polygonal, transparent structures without visible nuclei. The **staining characteristics of the cytoplasm** in cytologic preparations presumably depends on the species of keratin filaments. The cytoplasm of the superficial cells is usually eosinophilic. The cytoplasm of cells from the lower cell layers is usually basophilic. These staining properties may be modified by exposure to air-drying, which often results in a tinctorial change from basophilic to eosinophilic.

Figure 5-4 Diagrammatic representation of a squamous epithelium (other than epidermis of the skin), comparing the morphologic designation of cell types and their derivation from various epithelial layers.

Other Protective Epithelia

Variants of squamous epithelium, often highly specialized, may be observed in a variety of organ systems, for example, in the lower urinary tract and the larynx. The special features of these epithelia and the cells derived therefrom are described in the appropriate chapters.

Epithelia With Secretory Function

Histology

These epithelia are found mainly in organs with secretory functions and **exchanges with the external environment**,

P.123

such as food intake, **principally in the digestive tract and associated glands**. Similarly structured epithelia also occur in other locations, such as the male and female genital tracts. Secretory epithelia that **line the surfaces of organs**, such as the intestine and the endocervix, form **invaginations or crypts**, or may be organized in **glands** connected with the surface by **ducts**. Single cells of secretory type may also occur as a component of other epithelial types, for example, as **goblet cells** in the ciliated epithelium of the respiratory tract (see Fig. 5-1).

Figure 5-5 Mature squamous cells characterized by production of a large, resilient cytoplasmic surface. The condensed (pyknotic) nucleus is comparatively small. This cell type is eminently suited for the exercise of protective function. (Human buccal epithelium.)

Secretory epithelia are usually made up of a **single layer of cuboidal or columnar cells with a clear or opaque cytoplasm and vesicular nuclei** (see Figs. 5-1 and 5-6). The nuclei are

often located at the periphery of the cells, away from the lumen of the organ. The cytoplasm contains the products of cell secretion, such as mucus. The replacements for such epithelial cells are provided by small, intercalated **basal cells (reserve cells)**, which, under circumstances not clearly defined, replace obsolete glandular cells. The third component of secretory epithelia **observed only in glands and ducts**, such as salivary glands and ducts, is a peripheral layer of elongated cells with contractile properties, known as the **myoepithelial cells** (see Fig. 5-1). The function of the myoepithelial cells is to propel the product of cell secretions into excretory ducts and beyond.

Ultrastructural features of secretory epithelia were discussed in Chapter 2. The cells are provided with a large **Golgi apparatus** wherein the synthesis of the products of secretion takes place. The superficial cells form **tight junctions** that protect the internal environment of such epithelia.

Cytology

When well preserved, the secretory cells are **cuboidal or columnar** in shape, averaging from 10 to 20 μm in length and 10 μm in width. Their **cytoplasm is transparent** because of accumulation of products of secretion, usually mucus (Fig. 5-7). The products of secretion are packaged in small cytoplasmic vacuoles. It is important to note that secretory cells are often **polarized**, that is, they display one flat surface facing the lumen of the organ. Through that surface, the cells products are discharged. The **nuclei** of the secretory cells are **open (vesicular)**, averaging about 8 μm in diameter. The nuclei are either clear (transparent) or show moderate granularity, and are often provided with **small nucleoli**. The cytoplasm of cells derived from secretory epithelia is fragile and difficult to preserve. Thus, when these cells are removed from their site of origin, they often have poorly demarcated borders and their shape may be distorted. The cytoplasm of most secretory cells accepts pale basophilic stains.

Figure 5-6 Columnar epithelium of normal human colon. Note the opaque columnar cells and very many clear goblet cells. (H & E.)

Figure 5-7 Mucus-secreting endocervical cells. The cytoplasm of these cells is filled with mucus, which remains unstained. The nuclei are pushed to the periphery. Compare with electron micrographs of somewhat similar cells (see Figs. 1-15 and 1-19). This is a good example of a glandular cell with the cytoplasmic features geared to excretory function.

The myoepithelial cells are seen **only in aspirated samples** and are recognized by their small, comma-shaped, dark nuclei, surrounded by a very narrow rim of cytoplasm (see Chap. 29).

Ciliated Epithelia

Histology

The ciliated epithelia are characterized by **columnar, rarely cuboidal cells with one ciliated surface** that is facing the lumen of the organ. Such cells occur mainly in the **respiratory tract**, where they line the bronchi (see Fig. 1-4 and Chap. 19) but may be also found in the **endocervix**, the **fallopian tube**, and the **endometrium** during the secretory phase. As an incidental finding, ciliated cells may be **occasionally observed in almost any secretory epithelium**. Very often, the ciliated cells are accompanied by secretory cells that produce mucus or related substances, for example, **goblet cells** in the respiratory tract (see Fig. 5-1). The ciliated epithelia are often **stratified**, that is, composed of several layers of cells but, as a rule, the cilia develop only on the superficial cells facing the lumen. Such epithelia also contain small, intercalated **basal cells or reserve cells**, which are the source of regeneration of the epithelial cells.

The **cilia** are mobile structures, normally moving in unison in a single direction. In the respiratory tract, the ciliated bronchial cells are covered with a layer of mucus, which is propelled by the cilia in a manner similar to a moving sidewalk.

Particles of dust or other inhaled foreign material are trapped in the mucus (see Chap. 19).

Cytology

The recognition of ciliated cells is easy. These cells are usually of **columnar**, less often of **cuboidal configuration**, and have **one flat surface** on which the cilia are readily visible under the microscope (see Figs. 1-4 and 5-1). The cilia are anchored in **basal corpuscles** that form a distinct dense layer (**terminal plate**) near the flat cell surface. If the cilia are destroyed, the presence of a flat cell surface provided with a terminal plate may be sufficient to recognize ciliated cells. Usually, the **cilia have a distinct eosinophilic appearance that differs from the usually basophilic cytoplasm**. The length and width of these cells vary. The ciliated cells of the respiratory tract measure about 20 to 25 μm in length and about 10 μm in diameter. Other ciliated cells may be smaller.

In the respiratory tract, the columnar cells usually show one flat, cilia-bearing surface and a comma-shaped, narrow cytoplasmic tail, representing the point of cell attachment to the epithelium (see Fig. 5-1 and Chap. 19). The clear or somewhat granular vesicular **nuclei**, measuring about 8 μm in diameter, are usually located closer to the narrow, whip-like end of the cells. In other organs, the ciliated cells may be of cuboidal configuration and have more centrally located nuclei of a similar type.

It is of importance to note here that ciliated cells **are very rarely observed in cancer**.

Mesothelia

Histology

Organs contained within body cavities, such as the lung, the heart, and the intestine, are all enclosed within protective sacs lined by specialized epithelia of mesodermal origin. These sacs, known as the **pericardium** for the heart, **pleural cavity** for the lungs, and **peritoneal cavity** for the intestine, are lined by an epithelium composed of a single layer of flat cells, known as **mesothelial cells**. The sacs are closed and, therefore, the epithelial layer is uninterrupted, lining all surfaces of the cavity (Fig. 5-8A). Under normal circumstances, the **sacs are filled with only a thin layer of fluid** that facilitates the gliding of the two surfaces of mesothelial cells against each other (see Fig. 5-8B). It is the **function of the mesothelial cells to regulate the amount and composition of this fluid**. Therefore, the mesothelial cells are **osmotic pumps** provided with pinocytotic vesicles and microvilli on both flat surfaces.

Figure 5-8 Diagrammatic representation of mesothelial sacs, using the pleural cavity as example. The cavity is actually a potential space between the two layers of pleura that enclose the lung (*A*). The *circled area* is shown in detail in a histologic cross section (*B*) and as a sheet of mesothelial cells in a cytologic preparation (*C*).

Under abnormal circumstances, when the amount of fluid in the body cavity is increased (a condition known as **effusion**), the two opposing layers of the mesothelium separate, and the mesothelial cells may form a **multilayered epithelium** composed of larger, cuboidal cells (see Chap. 25).

Cytology

Upon removal from one of the body cavities, the cuboidal mesothelial cells may form sheets or clusters, in which the adjacent, flattened surfaces of the cells are separated from each other by clear gaps (“**windows**”) filled by microvilli (Fig. 5-8C). When these cells appear singly, they are usually spherical and measure about 20 μm in diameter. The **perinuclear portion of the cytoplasm of mesothelial cells is usually denser than the periphery** because of an accumulation of cytoplasmic organelles and filaments in the perinuclear location (see Chap. 25). The clear or faintly granular nuclei of mesothelial cells are usually spherical, measuring about 8 μm in diameter. Occasionally, tiny nucleoli can be observed.

Nonepithelial Cells

Endothelial Cells

Endothelial cells lining the intima of blood vessels have many similarities with mesothelial cells but are very rarely observed in diagnostic cytology, except in aspirated samples and in circulating blood (see Chaps. 28 and 43). These cells are best recognized in capillary vessels or as a layer of elongated cells surrounding sheets of epithelial cells. They may be immunostained with **clotting Factor VIII**.

Tissues With Highly Specialized Functions

There are numerous specialized types of tissues in the body.

These are found, for example, in the **central nervous system**; in the **endocrine glands**, such as thyroid or the adrenal cortex; in highly specialized organs, such as the **kidney, liver, pancreas**; and in the **reproductive organs**. Their description can be found in appropriate chapters.

Supporting Systems

A complex multicellular organism cannot function without an appropriate **supporting apparatus** that includes structural support and a well-regulated **system of transport, communications, and defense**. Many of the supportive functions are vested in tissues such as the muscles, nerves, bone marrow and cells derived therefrom, which are described as needed in various chapters. However, the system of defense (immunity) is of interest in the context of this book. The fundamental significance of the **immune system** has received renewed emphasis within recent times when the **acquired immunodeficiency syndrome (AIDS)** became

tumor (Kaposi's sarcoma), which becomes a highly aggressive neoplasm, and have low resistance to multiple infectious agents with resulting death. An understanding of the basic features of cells of the immune system in human cytology is sufficiently important to provide a brief summary of the salient facts.

The Immune Cell System

The basic concepts of the mechanism of resistance to diseases (immunity) were outlined by Metchnikoff at the turn of the 20th century. The recent years brought with them major progress in our understanding of the role that certain cellular elements play in immunity. A major review of the current understanding of the makeup and function of the immune system can be found in articles by Delves and Roitt (2000).

Immunology may be defined as the study of an organism's response to injury, particularly if the latter is due to foreign and harmful agents, for example, bacteria or viruses. **Immunity** is a natural or acquired state of resistance to diseases or disease agents, and it comprises all mechanisms that play a role in the identification, neutralization, and elimination of such agents. Although, in most instances, immunity has for its purpose the preservation of the host organism, certain immune processes may be injurious, not only to the disease agents but also to the host. Furthermore, the host may become immune to certain components of **self**, with resulting **autoimmune disorders** or diseases. **Loss of immunity** may be congenital (**primary**) or **secondary**, caused by pathologic events, such as HIV-1 infection in AIDS. For a review of primary immunodeficiencies, see Rosen et al, 1995.

Immunity has two broad components: cellular and humoral. Although both have the same purpose, namely, the protection of the host, their modes of action are different, even though they are dependent on each other. The **cell-mediated immunity**, vested primarily in T lymphocytes, is directed mainly against primary viral infections and against foreign tissues (such as transplants). **Humoral immunity**, vested primarily in B lymphocytes, acts primarily against bacterial infections. **Macrophages (histiocytes)**, cells with phagocytic function, are the third family of cells involved in the function of the immune system. The activities of the **T and B lymphocytes** and of the macrophages are closely integrated by an intricate system of chemical **signals, known as lymphokines or cytokines**. The failure of one of the links in this complex interrelationship may result in severe clinical disorders, such as AIDS. A brief and highly simplified account of the basic cellular components of the immune system and their interaction is provided below.

Figure 5-9 Cytospin preparation of a lymphocyte suspension from a normal human

tonsil, using an anti-lambda (*A*) and anti-kappa (*B*) antibody and peroxidase-antiperoxidase stain. Cells expressing lambda- or kappa-light chains (dark periphery) are B lymphocytes.

The Lymphocytes

Until about 1970, the lymphocytes were thought to represent a single family of cells, recognized as small, spherical cells (about 8 µm in diameter), with an opaque, round nucleus, and a narrow rim of basophilic cytoplasm. Within the past 30 years, enormous progress has been made in subclassification of lymphocytes and in understanding their life cycle and function. There are two principal classes of lymphocytes: the B lymphocytes and the T lymphocytes.

B Lymphocytes

The family of B lymphocytes was first identified by immunocytochemistry. With labeled monoclonal **antibodies to immunoglobulins**, it could be verified, first by fluorescence technique and, subsequently, by the peroxidase-antiperoxidase technique that some, but not all, lymphocytes secreted immunoglobulins (Fig. 5-9). The immunoglobulin-secreting cells were first observed in chickens provided with a large perianal lymphoid organ, known as the **bursa of Fabricius** (Parson's nose). The bursa was shown to be the organ of origin of these cells; hence, they were named **B lymphocytes or B cells**. The B lymphocytes can also be characterized by several **clusters of differentiation** based on features of the cell membrane (see below).

The end stage of maturation of B cells is the **plasma cell**, known to be programmed to secrete one single type of immunoglobulin. The puzzle to be solved pertained to the mechanisms that enabled B cells to recognize, from the vast diversity of antigens, that one which would lead to the

P.126

formation of a specific immunoglobulin directed against this antigen.

Immunoglobulins are composed of four protein chains: two **heavy chains** and two **light chains**, the latter designated as **kappa (κ)** and **lambda (λ)** (see Chap. 45). Each one of the four chains has a **constant component**, common to all immunoglobulins, and a **variable region** that reflects the specificity of the molecule. The variable region of the light chains is the "recognition region," capable of identifying one of a broad variety of antigens.

In humans, the B cells originate in the bone marrow **from stem cells**, common to all hematopoietic cells. The cells develop by a series of fairly well-defined stages, prior to their release into general circulation, from which they populate primarily the **lymphoid organs** (e.g., the lymph nodes and the spleen). The most important development in the understanding of B cells was the mechanism of their immunologic diversity. Tonegawa (1983) proposed that, during the development of the B cells, a series of **gene rearrangements** occurs, resulting in many thousands of diverse B cells, each with the specific capability of recognizing a different antibody. The genes, known as **D** (diversity), **J** (joining), and **V** (variable region) for the heavy chains and **V** and **J** for the light chains, are located on several chromosomes: chromosome 14 (encoding the heavy chains), chromosome 2 (encoding the κ-light chains), and chromosome 22 (encoding the λ-light chains). It could be documented that there are several D and J genes and several hundred V genes, for both the heavy and the light chains. It is clear that this diversity of genes allows an almost astronomical number of variations in the programming of a B cell, each

containing one VDJ gene combination for the heavy chain and a VJ combination for the light chain. **Each B cell is programmed to produce one antibody, which is expressed on the surface of the cell** (review in Stavnezer, 2000).

The principal groups of antibodies belong to several groups of immunoglobulins, each with a different immunologic advantage. The **IgM** antibodies stimulate phagocytosis and bacterial killing; **IgG** antibodies stimulate phagocytosis; **IgA** antibodies protect mucous membranes against invaders; **IgE** antibodies play a role in the elimination of parasites by activating eosinophils leading to release of histamine.

This diversity of B cells enables them to recognize most antigens that they may encounter; if the “fit” of the antibody is not perfect, a further somatic mutation may occur in the B cells, searching for a perfect fit. Once a correct antigen-antibody match is found, the B cell (with the help of specialized T cells) may reproduce itself in its own image and create a clone of cells directed against the specific antigen. Mission accomplished, the B cells will die, with the exception of a few “**memory cells**” that may persist and be called into action again if the same invader (antigen) threatens the system.

The various stages of B lymphocyte maturation in the bone marrow have also been recognized, because each is fairly accurately characterized by morphologic and immunologic changes. The recognition of the maturation stages of the B cell is the basis for contemporary classification of malignant proliferation of lymphocytes, such as leukemias or malignant lymphomas (see below and Chap. 31).

Plasma Cells

Plasma cells are the end stage of the development of B cells and are **major providers of specific immunoglobulins**. Normal plasma cells are somewhat larger than lymphocytes and are morphologically readily recognized because of their eccentric nucleus with a spoke-like arrangement of chromatin (Fig. 5-10). The cytoplasm contains an accumulation of immunoglobulins that may form eosinophilic granules or **Russel's bodies**. As is consistent with their secretory status, the plasma cells contain abundant rough endoplasmic reticulum, as seen in electron microscopy (see Chap. 2).

Malignant tumors composed of plasma cells are known as *myelomas* or *plasmacytomas*.

T Lymphocytes

The group of lymphocytes, known as T lymphocytes, was first recognized as a relatively small subset of lymphocytes (about 10% to 30%) that failed to react with antibodies to immunoglobulins characterizing B cells (see above). Subsequently, it was documented that this group of lymphocytes was derived from the **thymus**; hence, their designation as **T lymphocytes or T cells**. The next characteristic identified in T cells was their ability to form rosettes with sheep erythrocytes (Fig. 5-11), which documented that they also possess surface receptors, albeit different from those of B cells.

The T cells were also shown to be capable of **mitotic activity and proliferation in vitro**, when stimulated by plant-derived substances known as *lectins*. The lectins commonly used for this purpose are phytohemagglutinin, pokeweed agglutinin, and concanavalin A. **Stimulated resting T lymphocytes**

P.127

convert to lymphoblasts, large cells with large nuclei, often containing one or more visible

nucleoli.

Figure 5-10 Plasma cells in ascetic fluid (case of multiple myeloma). Note the characteristic eccentric position of the nuclei. May Grunwald Giesma stain, OM $\times 160$.

Figure 5-11 Human T lymphocyte surrounded by a rosette of sheep erythrocytes. (Oil immersion.)

Subsequent work showed that there are several **subtypes of T cells**. The gene rearrangements, described for B cells, also occur in T cells. The subtypes of T cells can be identified by antibodies to their membrane receptors (epitopes), known as **clusters of differentiation (CD)** (see below). The two most important subtypes are the **helper-inducer group**, also known as the **CD4 or T4 lymphocytes**, and the **suppressor-cytotoxic group**, also known as the **CD8 or T8 lymphocytes** (see Table 5-1). The cytotoxic cells are capable of destruction of foreign tissue and virus-infected cells. A third important group of T lymphocytes is the “**natural killer cells**” (NK cells).

The T lymphocytes are also capable of recognizing molecules belonging to the bearer (the so-called **human leukocyte antigen or major histocompatibility complex [HLA]**) and, thereby, are essential in prevention of immunologic response to “self.” For a major review of the HLA system, see Klein and Sato, 2000.

The principal role for the T lymphocytes in the immune system is **coordination of the activities of the entire immune system** by means of substances known as **lymphokines, cytokines, or interleukins**. These substances can **stimulate the growth of the bone marrow cells (hemopoietic colony-stimulating factor)**, **stimulate macrophages**, and **control the maturation of B lymphocytes**. Severe damage to a subset of T lymphocytes may produce a major defect in the immune response of patients. As mentioned above, the

destruction of the T4 (helper-inducer group) by the human immunodeficiency virus type I (HIV-1) leads to AIDS. Robert and Kupper (1999) summarized the current state of knowledge of T cells.

Recognition of various types and subtypes of lymphocytes has led to the contemporary classification of **malignant lymphomas**, discussed in Chapter 31.

The Cluster of Differentiation (CD) System

Research into the diversity of lymphocytes has led to the discovery of numerous **antibodies to various stages of lymphocyte development** and function. These antibodies correspond to **clusters of differentiation (CD), epitopes (receptors) found on the membranes of these cells**. The CDs are numbered and have various degrees of specificity. There are more than 1,000 different antibodies to well over 100 CDs. Some of the antibodies were mentioned above: the CD 4 antibody recognizing the “helper” T cells and CD 8 recognizing the “suppressor” T cells. It is beyond the scope of this chapter and this book to list all of the CDs available today. A few of the most commonly used CDs in cytologic preparations are listed in Table 5-1. It is particularly important to recognize that different laboratories may use differently numbered CDs for the same purpose, which, in most cases, reduces itself to two questions: **(1) Is the cell population of lymphocytic origin? and (2) If the answer to the first question is positive, what is the precise characterization of the disorder?** The significance of this approach is of value in diagnostic cytology of poorly differentiated tumors and in classification of malignant lymphomas and leukemias. The reader is referred to appended references and to Chapters 31 and 45 that describes the value of these antibodies in practice of diagnostic cytology.

The Macrophages (Histiocytes)

In 1924, Aschoff described the **reticuloendothelial system** as a variety of cell types occurring in many organs that participate in body defenses by **phagocytosis**. The cells of the **reticuloendothelial system comprise immobile and mobile cells**. The immobile cells, such as the endothelial cells or Kupffer cells in the liver, respond to the local needs

P.128

of the organ wherein they are located. **The mobile cells are the macrophages or histiocytes.**

TABLE 5-1 CLUSTERS OF DIFFERENTIATION

Selected Cluster of Differentiation	Distribution
CD2	T cells, NK subset
CD3	Thymocytes and mature T cells
CD4	Helper/inducer T cells, monocytes
CD5	T cells, B-cell subset, brain

CD7	Earliest T-lineage marker, most T cells, NK cells, ALL, 10% AML
CD8	Suppressor/cytotoxic T cells, NK subsets
CD10	Early B and T precursors, pre-B ALL, granulocytes, kidney epithelium (CALLA)
CD15	Granulocytes, Reed-Sternberg cells
CD20	B cells
CD30	Activated B and T cells, Reed-Sternberg cells carcinoma
CD45	Leukocyte common antigen, multiple isoforms
CD56	NK, T subset
CD138	Plasma cells (not mature B cells)

NK, natural killer cells; B CLL, B-cell chronic lymphocytic leukemia;

AML, acute myeloblastic leukemia; ALL, acute lymphocytic leukemia;

CALLA, common acute lymphoblastic leukemia antigen.

(Courtesy of Dr. Howard Ratech, Montefiore Medical Center.)

The **macrophages**, which are characterized by their **capacity to engulf (phagocytize)** foreign particles, such as bacteria, fungi, protozoa, and foreign material, may achieve very large sizes and, therefore, are highly visible in light microscopy. The term *macrophage* (i.e., a cell capable of engulfing large particles) was originally suggested for this group of cells by Metchnikoff, to **differentiate them from polymorphonuclear leukocytes capable of engulfing only very small particles (microphages)**. The term *histiocyte* was originally coined to suggest cells with properties similar to those of macrophages, yet found predominantly in tissues. The two terms are used interchangeably, although the current trend is to favor the term *macrophage*. Both terms will be used simultaneously in this work to acknowledge wide usage of the terms *histiocyte* and *histiocytosis* in pathology. The inability of macrophages to perform the phagocytic function results in a number of life-threatening disorders (Lekstrom-Himes and Gallin, 2000).

Current evidence suggests that **macrophages are derived from monocytes of bone marrow origin** (see Chap. 19). The actual differentiation and maturation of macrophages takes place in the target tissue. The activation of precursor cells into macrophages is mediated by T lymphocytes by means of specific soluble factors or lymphokines. The changes occurring

during activation may be conveniently observed in tissue cultures in vitro. The round, small precursor cells become markedly enlarged when spread on glass and acquire a number of dense cytoplasmic granules, which have been identified as lysosomes by electron microscopy (Fig. 5-12).

Figure 5-12 Unstimulated and stimulated rat peritoneal macrophages in tissue culture (phase contrast microscopy). *A.* Unstimulated macrophage. The cell is small, rounded, and shows no cytoplasmic activity of note. The nucleus is central. *B.* Stimulated macrophage. Note the large size of the cell containing numerous lysosomes that appear as dark cytoplasmic granules. The nucleus is eccentric. ($\times 4,400$.) (Adams DD, et al. The activation of mononuclear phagocytes in vitro: Immunologically mediated enhancement. *J Reticuloendothel Soc* 14:550, 1973.)

Once differentiated, the **macrophages in the tissue may remain mobile** or may lose their mobility and become **fixed**. This occurs particularly in certain chronic inflammatory processes, such as tuberculosis. In the latter situation, the macrophages **assume an epithelial configuration** in clusters or sheets (**epithelioid cells**), usually accompanied by **multinucleated giant cells**.

In diagnostic cytology, macrophages play an important role and their recognition is sometimes essential. **Macrophages may be mononucleated or multinucleated. Mature mononucleated macrophages** in light microscopy are cells of variable sizes. The nucleus is round or kidney-shaped. The cytoplasm is filled with small vacuoles but often contains granules or fragments of phagocytized material. In actively phagocytizing cells, the nucleus is often peripheral (Fig. 5-13A). In scanning electron microscopy, the macrophages have been shown to have surfaces provided with flanges and ridges that are fairly characteristic of these cells (see Chap. 25).

The **multinucleated macrophages (polykaryons)** result from fusion of mononucleated macrophages and may reach huge sizes (Mariano and Spector, 1974). In some of these cells, the nuclei are arranged at the periphery in an orderly fashion (**Langhans' or Touton's cells**). In

other multinucleated macrophages, the nuclei are dispersed throughout the cytoplasm (Fig. 5-13B).

Macrophages are activated by lymphokines from specifically sensitized T lymphocytes. Activated macrophages are

P.129

also capable of secreting numerous products that, in turn, may regulate functions of lymphocytes and help in disposing of phagocytized particles.

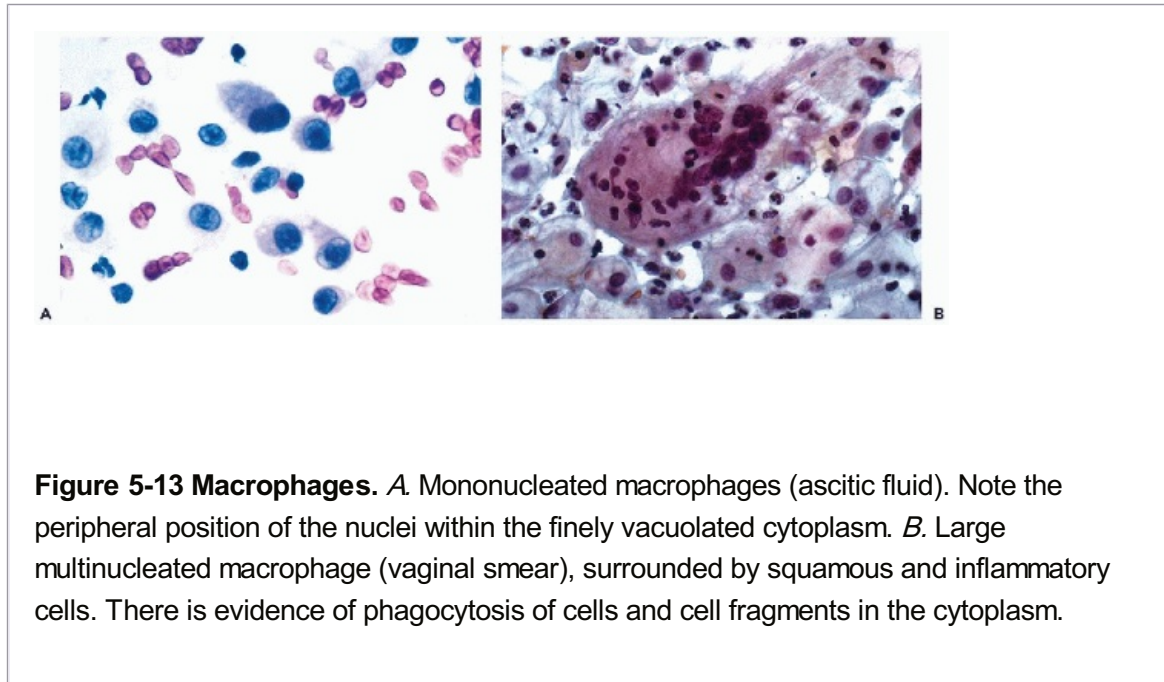

Figure 5-13 Macrophages. *A.* Mononucleated macrophages (ascitic fluid). Note the peripheral position of the nuclei within the finely vacuolated cytoplasm. *B.* Large multinucleated macrophage (vaginal smear), surrounded by squamous and inflammatory cells. There is evidence of phagocytosis of cells and cell fragments in the cytoplasm.

Macrophage deficiencies have been observed in AIDS wherein these cells may be infected by HIV-1. In some situations, **close contacts between macrophages and cancer cells** have been observed (Fig. 5-14). The significance of these observations is not clear.

Phagocytic Properties of Cells Other Than Macrophages

Wakefield and Hicks (1974) have shown that, under certain experimental circumstances, cells of bladder epithelium are capable of phagocytosis of erythrocytes. It is also known that cells of endometrial stroma may acquire phagocytic properties at the time of menstrual bleeding. Sporadic examples of phagocytosis by benign and malignant cells have been observed. Little is known about the biologic circumstances that lead to these events.

Figure 5-14 Scanning electron micrograph of an extensive contact between a macrophage, shown as a large cell characterized by surface ruffles, and a small lymphocyte with surface covered by microvilli. (Pleural effusion. Approx. $\times 4,000$.) (Courtesy of Dr. W. Domagala, Montefiore Hospital, New York.)

Cancers Derived From the Immune Cell System

The observations summarized above have led to further characterization of the origin of many malignant diseases derived from cells that constitute the immune cell system. Most **chronic lymphocytic leukemias, non-Hodgkin's lymphomas, Burkitt's lymphomas, and all Waldenström's macroglobulinemias are of B-cell origin**, whereas the neoplastic cells of some **non-Hodgkin's lymphomas**, the rare **Sézary syndrome**, and 1% to 2% of patients with **chronic lymphocytic leukemia** are of **T-cell origin**. **Multiple myeloma is derived from plasma cells**. The cells of leukemic reticuloendotheliosis and histiocytic medullary reticulosis are thought to arise from macrophage precursors. For further comments on classification of lymphomas, see Chapter 31.

The Blood Cells

Only a brief mention of blood cells will be made here. **Erythrocytes** and **leukocytes** may be found with reasonable frequency in cytologic material and knowledge of their morphologic features is essential. Since hematology is not a part of this book, the reader is referred to other sources for a more detailed discussion.

Well-preserved **erythrocytes** in cytologic material indicate fresh bleeding, resulting from breakage of blood vessels. This injury may be due either to a physiologic process, such as

menstrual bleeding, a disease process, a mechanical trauma, or iatrogenic procedure.

As a rule, the **neutrophilic polymorphonuclear leukocytes** are associated with **acute inflammatory processes**. In small numbers, they may be physiologically present in cytologic material of various origins.

P.130

Eosinophilic polymorphonuclear leukocytes (eosinophils) are associated with **allergic processes**, such as asthma or hay fever or response to a **parasitic infection**. In other situations, the role of **basophilic polymorphonuclear leukocytes (basophils)** remains **obscure**. **Megakaryocytes** may be observed in cytologic material, as described in Chapters 8, 19, 25, 30, and 47.

6

Morphologic Response of Cells to Injury

The purpose of diagnostic cytology is to **recognize processes that cause cell changes that are identifiable under the light microscope**, supplemented, when necessary, by cytochemistry, immunocytochemistry, electron microscopy, or molecular biologic techniques (see Chaps. 2, 3, and 45). In this chapter the causes and effects of various forms of injury to the cells are discussed. Benign and malignant neoplasms (tumors) will be discussed in Chapter 7.

CAUSES OF CELL INJURY

Injury to the cells may be caused by numerous agents and disease states. A brief listing of the most significant sources of recognizable cell abnormalities observed in diagnostic cytology is as follows:

I. Physical and Chemical Agents

- A. Heat
- B. Cold
- C. Radiation
- D. Drugs and other chemical agents

II. Infectious Agents

- A. Bacteria
- B. Viruses
- C. Fungi
- D. Parasites

III. Internal Agents

- A. Inborn, sometimes hereditary genetic defects of cell function
 - 1. Storage diseases (e.g., Tay-Sachs and Gaucher's diseases)
 - 2. Metabolic disorders (e.g., phenylketonuria)
 - 3. Faulty structure of essential molecules (e.g., sickle cell anemia)
 - 4. Miscellaneous disorders
- B. Diseases of the immune system
 - 1. Inborn immune deficiencies

2. Acquired immune deficiencies
3. Autoimmune disorders

IV. Disturbances of Cell Growth

- A. Benign (self-limiting)
 1. Hyperplasia
 2. Metaplasia
- B. Tumors or neoplasms (**see Chap. 7**)
 1. Benign
 2. Malignant

P.132

CELLULAR RESPONSE TO INJURY AT THE LIGHT MICROSCOPIC LEVEL

Cells have limited ability to express their response to injury. They may respond:

- **by dying** (necrosis or apoptosis)
- **by undergoing a morphologic transformation** that may be transient or permanent
- **by mitotic activity** that again may be either transient or sustained, normal or abnormal, and may result in normal or abnormal daughter cells and subsequent generations of cells.

Although the mechanisms of cellular responses to injurious agents are still poorly understood because they are the result of complex molecular changes, it appears reasonable to assume that **a cell will attempt to maintain its morphologic and functional integrity, either by mobilizing its own resources against injury, or by seeking assistance from other cells specializing in defensive action.** The latter type of response is triggered by cell **necrosis**, a form of cell death, which results in an **inflammatory process**, with participation of leukocytes and macrophages. The significant morphologic responses of cells to various forms of injury are summarized below.

CELL DEATH

In cells, as in all other forms of life, death is an inevitable event. Death may follow a specific programmed pathway, or it may occur as an incidental event. Programmed cell death was first described and named **apoptosis** (from Greek, *apo* = from and *ptosis* = falling or sinking) by Kerr et al in 1972 (see also Searle et al, 1982 and Kerr et al, 1994). Apoptosis was first recognized as a purely morphologic phenomenon affecting cells, to be differentiated from **necrosis**, a form of cell death that occurred incidentally caused by an event or events not compatible with cell survival. The sequence of events in the two processes is compared in Figure 6-1. Within the recent years, apoptosis has received an enormous amount of attention from molecular biologists because of its importance in developmental biology and in a number of diseases, such as stroke and cancer.

Apoptosis

Morphology

The most significant studies of apoptosis in man have been conducted on cells in culture or on lymphocytes. There is comparatively little information on apoptosis in epithelial cells. Apoptotic cells are characterized by nuclear and cytoplasmic changes. The nuclear changes are a **condensation of the nuclear chromatin, first as crescentic caps** at the periphery of the nucleus, **followed by further fragmentation** and break-up of the nucleus (Fig. 6-1 top). The fragmentation of the chromatin into small granules of approximately equal sizes is known as **karyorrhexis** (from Greek, *karyon* = nucleus, *rhexis* = breakage), which has now been recognized as a manifestation of apoptosis (Fig. 6-2). The cytoplasm of many apoptotic cells may show shrinkage and membrane blisters. It appears, however, that the cytoplasm may remain relatively intact in squamous cells. As the next stage of cell disintegration, fragments of nuclear material with fragments of adjacent cytoplasm (that may contain various organelles) are packaged into membrane-enclosed vesicles (**apoptotic bodies**). These packages of cellular debris are phagocytized by macrophages, **without causing an inflammatory reaction** in the surrounding tissues. One important consequence of apoptosis is that the cell DNA is chopped up into fragments of variable sizes composed of **multiples of 185 base pairs**. When sorted out by electrophoresis, they form a “**DNA ladder**” of fragments of diminishing sizes. Because the breaks occur at specific points of nucleotide sequences, they can be recognized by **specific probes identifying the break points in the DNA chain**. The probes, either labeled with a fluorescent compound or peroxidase, allow the recognition of cells undergoing apoptosis, either by fluorescent microscopy, flow cytometry, or by microscopic observation (Li and Darzynkiewicz, 1999; Bedner et al, 1999). A so-called **TUNNEL** reaction is a method of documenting apoptosis in cytologic or histologic samples (Gavrieli et al, 1992; Li and Darzynkiewicz, 1999; Sasano et al, 1998).

Sequence of Biologic Events

In paraphrasing a statement by Thornberry and Lazebnik (1998), apoptosis is reminiscent of a well-planned and executed military operation in which the target cell is isolated from its neighbors, its cytoplasm and nucleus are effectively destroyed, and the remains (apoptotic bodies) are destined for burial at sea, leaving no traces behind. Much of the original information on the sequence of events in apoptosis was obtained by studying the embryonal development events in the small worm (nematode), *Caenorhabditis elegans*. These studies have documented that apoptosis occurs naturally during the developmental stages of the worm to eliminate unwanted cells. It is caused by a **cascade of events**, culminating in the activation of proteolytic enzymes that effectively destroy the targeted cell. A somewhat similar, but not identical, sequence of events was proposed for mammalian cells.

Apoptosis in mammalian cells is triggered by numerous injurious factors, some known, such as viruses, certain drugs, radioactivity, and some still unknown (summary in Thompson, 1995; Hetts, 1998; review in Nature, 2000). For example, the loss of T4 cells by the human immunodeficiency virus in acquired immunodeficiency syndrome (AIDS) is caused by apoptosis. However, the pathway to apoptosis is extremely complicated because normal cells contain **genes that prevent it and genes that promote it**. This equilibrium has to be disrupted for the cells to enter the cycle of death.

In brief, it is assumed today that “death signals,” received by the cytoplasm of the cell and mediated by a complex sequence of molecules, lead to activation of proteolytic enzymes, known as **caspases** that destroy the cytoplasmic proteins, including intermediate filaments, and attack the nuclear lamins, causing the collapse of the nuclear DNA structure. However, the

intermediate steps of this sequence of events are enormously complicated. An injury to the molecule p53 (guardian of the genome; see Chap. 3) appears to be an important event (Bennett et al, 1998). Recent studies have documented that genes located on the **mitochondrial membrane** play a critical role in apoptosis (Brenner and Kroemer, 2000; Finkel, 2001). These genes belong to two families: **Bcl**, a protooncogene, which **protects the cells from apoptosis**, and **Bax**, which **favors apoptosis** (Zhang et al, 2000). If the proapoptotic molecule prevails, there is damage to the mitochondrial membrane with release of cytochrome C into the cytoplasm. Cytochrome C acts to transform a ubiquitous protein molecule known as *zymogen* into caspases.

Figure 6-2 Apoptosis. *A.* Apoptosis (karyorrhexis) of malignant lymphoma cells in an aspirate of lymph node. *B.* Apoptosis of cells of malignant lymphoma in bloody pleural effusion. (*B*, High magnification.)

Numerous articles on the subject of apoptosis have appeared in recent years, each addressing a small fragment of the complex puzzle. The key recent articles are cited or listed in the bibliography. The significance of apoptosis goes much beyond a simple morphologic and molecular biologic summary. It is generally thought that the mechanisms of apoptosis, besides playing a key role during embryonal development, may play a **key role in cancer and in important degenerative processes** such as Alzheimer's disease. In **cancer, suppression of apoptosis** may be one of the causes of cell proliferation, so characteristic of this group of disorders. This may explain the role of **oncogenes, such as Bcl or Myc**, as protecting the cells from apoptosis. It is considered that changes or mutations in molecules controlling DNA damage in replication (such as p53) or molecules governing events in the cell cycle (such as Rb) play a role in these events. It has been proposed that, in degenerative disorders of the brain, such as Alzheimer's disease, apoptosis may destroy essential centers of memory and control of body functions.

Necrosis

Cells may also die as a consequence of nonapoptotic events, globally referred to as **necrosis**. Some of the known causes of necrosis are exposure to excessive heat, cold, or cytotoxic chemical agents. There is considerably less information on this type of cell death than on apoptosis, and the main difference is the **absence of typical morphologic changes and no evidence of activation of the cascade of events characterizing apoptosis** (see Fig. 6-1 bottom).

Morphology

Cells undergoing nonapoptotic forms of necrosis may show extensive **cytoplasmic vacuolization** (Fig. 6-3). The nuclear changes include homogeneous, dense chromatin known as **nuclear homogenization or pyknosis** (from Greek, *pyknos* = thick), nuclear enlargement, and break-down of nuclear DNA, which however, **does not form the DNA ladder**, characteristic of apoptosis. Necrosis may result in destruction of the cell membranes, resulting in disintegration of the cell and **formation of cell debris** leading to an inflammatory process. The nuclear material may form fragments or streaks, often recognizable because they stain blue with the common nuclear dye, hematoxylin. Similar events may occur by physical injury to fragile cells if they are inappropriately handled during the technical preparation of

smears or other diagnostic material. In some cancers, the presence of nuclear necrosis is widespread and may be of diagnostic value (see oat cell carcinoma in Chap. 20).

Figure 6-3 Radiation effect on squamous cells. Huge cytoplasmic vacuoles signify cell death. (High magnification.)

It is often quite impossible to determine morphologically whether a cell died as a consequence of apoptosis or necrosis. There is little doubt that there may be many pathways leading to cell death. What is significant, however, is **the role played by necrotic cells as a trigger of inflammatory events**, whereas cells dying of apoptosis, as a rule, do not cause any inflammatory reaction.

Sequence of Biologic Events

Cell necrosis may be caused by many of the types of cell injury listed in the opening page of this chapter. Thus, there is a significant overlap between the two modes of cell death. It is not known today why the differences in the mode of dying occurs if the trigger of cell death is the same. It is generally believed that cell necrosis may begin in a manner similar to apoptosis, that is, by activation of a cell membrane molecule or a “death signal,” which is followed by mitochondrial swelling, but this differs from the events in apoptosis because it **does not lead to caspase activation** (Green and Reed, 1998). Obviously, much is still unknown about cell necrosis, its mechanisms, and consequences.

OTHER EXPRESSIONS OF CELL RESPONSE TO INJURY

“Reactive” Nuclear Changes

It is not uncommon to observe, in material from various sources and under a variety of circumstances, but mainly in the presence of inflammatory processes, minor nuclear abnormalities such as **slight-to-moderate nuclear enlargement, slight irregularities of the nuclear contour, increase in granularity of the chromatin, and occasionally the**

presence of somewhat enlarged nucleoli (Fig. 6-4). Such abnormalities are often classified as “**reactive nuclear changes**.” Virtually nothing is known about the mechanisms of such changes and their clinical significance is often puzzling. In many situations, such nuclear abnormalities occur in tissues adjacent to cancer. In cervical smears, the terms *atypia of squamous cells of unknown significance (ASCUS)* or *atypia of glandular (endocervical) cells of unknown significance (AGUS)* have been introduced to describe such phenomena. The term AGUS is no longer used. It is known that, in some patients with such changes a malignant lesion will be observed in the uterine cervix with the passage of time (see Chap. 11). Similar abnormalities may be observed in the so-called **repair reaction** and in **metaplasia**, discussed below. Thus, the term **reactive nuclear changes** is rather meaningless and reflects our ignorance of events leading to such nuclear abnormalities.

Figure 6-4 Reactive squamous cells. Note the presence of large nuclei and of prominent nucleoli in what is commonly referred to as a “repair reaction.”

Multinucleation: Formation of Syncytia

It is not known why reaction to injury results in formation of multinucleated cells. These may occur as a consequence of a bacterial or viral infection, during a regenerative process, as in injured muscle, or for reasons that remain obscure. Multinucleation may be observed in cells of various derivations, such as macrophages, cells derived from organs of mesenchymal origin, or in epithelia.

The mechanism of formation of multinucleated cells by epithelioid cells was discussed in Chapter 5. Under unknown circumstances, apparently **normal epithelial cells** may form **multinucleated giant cells or syncytia** (from Latin, *syn* = together and *cyto* = cell) by cell fusion or **endomitosis**, that is, nuclear division not followed by division of the cytoplasm.

Regardless of mechanism of formation, such cells may be observed in the bronchial epithelium (see Chap. 19) and, occasionally, in other glandular epithelia (Fig. 6-5). In multinucleated cells caused by cell fusion, the cell membranes separating the cells from each other disappear.

Multinucleation can be produced **in vitro** by the action of certain viruses, such as the Sendai virus, and **in vivo** in humans by herpesvirus and other viral infections. Thus, it is conceivable that the formation of true syncytia in epithelial cells is the reflection of a viral infection, although the causative agent may not be evident. To our knowledge, there is **no known diagnostic or prognostic significance** of the presence of

P.136

multinucleated epithelial cells. Such cell changes **must not be confused with cell groupings or clusters, wherein cell membranes may not be visible under the light microscope, but are easily demonstrated by electron microscopy.** The term *syncytia* has been proposed by some observers to define clusters of small cancer cells in cervical smears in some cases of carcinoma in situ of the uterine cervix (see Chap. 12). The use of this term under these circumstances is erroneous.

Figure 6-5 Multinucleation of benign ciliated bronchial cells. Note the presence of three nuclei in one of the cells and innumerable nuclei in a large cell on the left. (High magnification.)

Other Forms of Cell Injury

Nuclear abnormalities, seen in healthy or diseased tissue, are **nuclear creases or grooves**, folds observed in the nuclei of many cell types, and in many organs. Frequent and conspicuous nuclear grooves may be observed in some benign and malignant tumors but are not tumor-specific. The significance or mechanism of this nuclear feature is unknown (see Chaps. 7, 8, 21, and 41).

Nuclear cytoplasmic inclusions, observed as a **sharply defined clear zone in the nucleus**, are more common in certain malignant tumors but may also occur in cells derived from normal organs (see Fig. 7-19A). It can be documented by electron microscopy that the abnormality is caused by **infolding of the cytoplasm into the nucleus** (Fig. 6-6B). The reason for the mechanism of these events is unknown.

Other manifestations of cell damage may include the **loss of specialized cell appendages, such as cilia**. The loss of cilia may occur in otherwise well-preserved cells or it may be accompanied by a peculiar form of cell necrosis, often associated with viral infection

(**ciliocytophthoria**) (see Chap. 19). **Loss of cell contacts** is another form of cell injury that may be caused, for example, by antibodies directed against desmosomes observed in skin disorders, such as pemphigus (see Chaps. 19, 21, and 34). It should be noted that, in cancer, the relationship of cells to each other is often quite abnormal as discussed at some length in Chapter 7.

Figure 6-6 Electron micrograph of an intranuclear cytoplasmic inclusion in a cell from renal carcinoma. Note cytoplasmic organelles within the nucleus. (High magnification.) (Courtesy of Dr. Myron Melamed, Valhalla, NY.)

Cytoplasmic Vacuolization

This phenomenon may reflect a partial or temporary disturbance in the permeability of the cell membrane, resulting in formation of multiple, clear, spherical cytoplasmic inclusions (**vacuoles**) **of variable sizes** (see Fig. 6-3). Most vacuoles contain water and water-soluble substances. The viability of such cells is unknown, although extensive vacuolization may be a manifestation of cell death, for example, caused by radiotherapy. Small cytoplasmic vacuole formation may also occur as a consequence of **cell invasion by certain microorganisms**, such as

Chlamydia trachomatis and other infectious agents (see Chap. 10). Storage of **fat** may also result in the formation of cytoplasmic vacuoles.

Cytoplasmic Storage

Under special circumstances, the cell may also store other products of cell metabolism that can be recognized under the light or electron microscope. Thus, **glycogen**, **bile**, **melanin pigment** (normally present in the epidermis of the skin and in the retina), and **iron**, derived from disintegrating hemoglobin molecules (**hemosiderin or hematoidin**) may accumulate in abnormal locations (see Fig. 7-24B). Another pigment, **lipofuscin**, thought to represent products of cell wear and tear, may also be seen, usually in perinuclear locations. Because hemosiderin, melanin, and lipofuscin form brown cytoplasmic deposits that may look similar under the light microscope, the use of special stains may be required for their identification (see Chap. 45). The identification of these pigments may be of critical significance in the differential diagnosis of a melanin-producing, highly malignant tumor, the malignant melanoma. Under some circumstances, **salts of calcium** may form irregularly shaped amorphous or concentrically structured deposits within the cytoplasm. Such deposits are usually recognized by their intense blue staining with hematoxylin. Also, a variety of **crystals**, either derived from amino acids or from inorganic compounds, may accumulate in cells. The implications of these findings is discussed in the appropriate chapters.

Storage Diseases

In a variety of inherited storage diseases, caused by deficiencies of specific lysosomal enzymes, such as Gaucher's disease, Niemann-Pick disease, von Gierke's disease, Tay-Sachs disease, Hand-Schüller-Christian disease, and other very rare disorders, the **products of abnormal cell metabolism** may accumulate, mainly in macrophages, but also in the cytoplasm of other cell types. As a general rule, such cells become markedly enlarged. Several of these disorders can be identified under the light microscope because of the specific appearance of the large cells. Some of these disorders may be recognized in aspirated cell samples and are discussed in Chapter 38. Most commonly, however, such cells are seen

P.137

in bone marrow samples. The description of the specific cell changes may be found in hematology manuals.

Figure 6-7 Diagrammatic representation of the stages of phagocytosis. (1) The foreign particle is trapped in a vesicle formed by invagination of the cell membrane. (2) It sinks into the depth of the cytoplasm, and (3) merges with a cytophagic vacuole (lysosome). (4) The enzymes contained in the cytophagic vacuole digest the foreign material. The mechanism is similar to that of pinocytosis.

Phagocytosis

Phagocytosis, or ingestion of foreign particles by cells, has already been discussed in Chapter 2. Although phagocytosis, strictly speaking, cannot be considered a form of cell reaction to injury, it is often enhanced in disease processes such as inflammation and cancer. The sequence of events in phagocytosis is shown in Figure 6-7. The cells principally involved in phagocytosis are the **macrophages**, which accumulate visible particles of foreign material in their cytoplasm (Fig. 6-8). Occasionally, however, **epithelial and mesothelial cells**, and particularly **cancer cells**, are also capable of the **phagocytic function** and may display the presence of foreign particles, cell fragments, or even whole cells in their cytoplasm. A special form of phagocytosis is **erythrophagocytosis**, in which whole red blood cells are engulfed by macrophages, but also sometimes by cells of other types (see Chap. 25). The precise mechanisms of these phenomena are now being studied (Caron and Hall, 1998). A special situation is represented by an uncommon disorder, **malacoplakia**, observed mainly in the urinary bladder but also in other organs. In it, the cytoplasmic lysosomes of macrophages lack certain enzymes necessary for the destruction of phagocytized coliform bacteria. As a consequence, the lysosomes become enlarged and readily visible as the so-called **Michaelis-Guttman** bodies. Such bodies may undergo calcification (see Chap. 22).

Figure 6-8 Phagocytosis of foreign material by macrophages. A so-called tingible body macrophage (arrow) in an aspiration smear from a normal lymph node.

Localized cell damage and death, resulting from physical or infectious causes, leads to a **replacement or regeneration** of the injured tissue, sometimes referred to as **repair**. The **source of replacement** is the neighboring cells of the same type. Thus, an epithelium will be replaced by epithelial cells and the regeneration of the connective tissue will be provided by fibroblasts. Theoretically, the growth of cells leading to regeneration should cease when the restoration of the injured tissue is complete. In practice, this is not always so: the newly formed tissue is sometimes less than perfect and its growth may continue beyond the confines of the original tissue, sometimes resulting in a hyperplasia, and even a so-called **pseudotumor**. Alternatively, a portion of the injured tissue may be replaced by collagen-forming connective tissue, with resulting formation of a **scar**. In experimental systems, regeneration has been exhaustively studied in the liver after partial hepatectomy and in the epithelium of the urinary bladder, after destruction with the cytotoxic drug, cyclophosphamide (see Chap. 22).

In general, the **first event in the regeneration process of the injured epithelium**, usually occurring within approximately 24 hours after the onset of injury, is an intense **mitotic activity** in the normal cells surrounding the injured tissue. Cell division is apparently triggered by biochemical signals, from the injured cells. The **mitotic activity in tissue repair is not always normal: abnormal mitotic figures may be observed**. The mitotic activity results in the formation of young epithelial cells that migrate into the defect to form **a single layer of epithelial cells bridging the gap** caused by the injury. With the passage of time, the epithelium becomes multilayered. The **newly formed young epithelial cells are often atypical** and are characterized by the

P.138

presence of a basophilic cytoplasm, reflecting the intense production of ribonucleic acid (RNA) and proteins in the rapidly proliferating cells. However, the most conspicuous finding in such cells is **nuclear abnormalities** in the form of large nuclei of uneven sizes, often provided with multiple, **large, and irregular nucleoli reflecting the cell's requirement for RNA** (see Fig. 6-4). Such cells may mimic nuclear and nucleolar abnormalities of cancer and are one of the **major potential pitfalls in diagnostic cytology**. The term *repair* has been proposed to define certain benign abnormalities observed in **endocervical cells** in cervical smears although, in many such cases, there is no evidence of prior epithelial injury. Similar changes may also be observed in other organs (see Chaps. 10, 19, and 21).

The reaction to injury may also involve **connective tissue**, with resulting intense proliferation of fibroblasts. The **proliferating fibroblasts are usually large and have a basophilic cytoplasm**, not unlike proliferating fibroblasts in culture. **Large nuclei and conspicuously enlarged nucleoli** are a landmark of such reactive changes. The presence of **abnormal mitotic figures** may be noted, resulting in patterns reminiscent of malignant tumors of connective tissue or sarcomas (Fig. 6-9). Such self-limiting abnormalities may occur in muscle, fascia, or subcutaneous tissue, and they are referred to as **infiltrative or pseudosarcomatous fasciitis**.

The **molecular biology** of tissue regeneration and repair has been shown to be extremely complex. It can be assumed, in general, that under normal conditions of regeneration, there are two sets of biochemical factors working in tandem: factors inducing mitosis and, thereby, stimulating cell proliferation and factors arresting the cell proliferation, once the repair has been completed. Studies of regeneration of hepatocytes (Michalopoulos and DeFrances, 1997), wound healing (Martin, 1997), and amphibian limb regeneration (Brockes, 1997) have shown the enormous complexity of the system. Numerous genes, perhaps activated by the initial

necrosis of the target tissue, enter into the equation, resulting in production of new cells and tissues. There is little known about the molecular signals that arrest the proliferative process upon completion of the repair. Some years ago, poorly characterized chemical factors, named *chalones*, were thought to be the “stop” signal, but essentially no information emerged within the recent years. The interested reader is referred to the bibliography for further information on this subject.

Figure 6-9 A benign reactive process known as infiltrative fasciitis. A. Note large fibroblasts with prominent nuclei and nucleoli. **B.** A quadripolar mitosis is evident in the center of the field.

The results of regeneration of repair are frequently far from perfect, particularly for epithelia, and may result in a number of abnormalities that will be described in the following sections.

BENIGN EPITHELIAL ABNORMALITIES CONSIDERED TO REPRESENT A REACTION TO CHRONIC INJURY

Basal Cell Hyperplasia

In this lesion, which may affect almost any epithelium, **the number of layers of small basal cells is increased**, so that up to one-half or even more of the epithelial thickness is occupied by small cells (Fig. 6-10). It is generally assumed, although it remains unproved, that basal cell hyperplasia is the result of a chronic injury. The **true significance of this abnormality and its mechanism of formation remain unknown**. It is sometimes assumed that this lesion is a precursor lesion of cancer, but the evidence for this is lacking. Because the events take place in the deeper layers of the epithelium, the cells resulting from the multiplication of the basal layer are not represented in samples obtained from the epithelial surface, unless there is an epithelial defect with loss of superficial cell layers. The lesion is of greater practical importance when the **small basal cells are removed by an instrument** or are found in an aspiration biopsy. Because of a large nuclear surface and, hence, an increased nucleocytoplasmic ratio (see Chap. 19), and the occasional presence of nucleoli, such cells may be sometimes mistaken for a malignant lesion composed of small cells.

Metaplasia

By definition, metaplasia is **the replacement of one type of epithelium by another** that is not normally present in

a given location. **In most instances, during the metaplastic process, a columnar or glandular epithelium is replaced by squamous epithelium or by cells with unusual characteristics, such as the mitochondria-rich oncocytes.** Metaplasia may occur as a result of an injury or chronic irritation caused by an inflammatory process or a mechanical trauma, for example, the pressure of a stone on an epithelium. With few exceptions, however, **the mechanisms of metaplastic replacement are generally not understood**, although lack of vitamin A may induce keratinization of epithelia in vivo or in vitro.

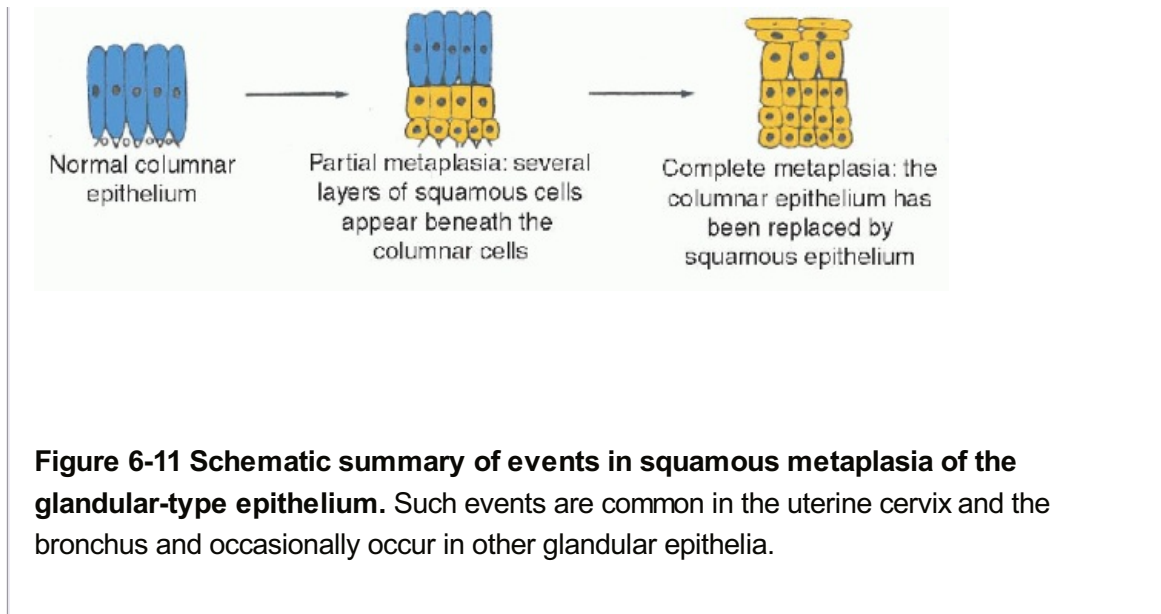

Figure 6-10 Schematic illustration of basal cell hyperplasia in squamous epithelium. The process may also involve other types of epithelia.

An example of metaplasia is the **replacement of the columnar mucus-producing epithelium** of the endocervix or of the ciliated bronchial epithelium **by squamous epithelium**, colloquially referred to as **squamous metaplasia** (Fig. 6-11). The epithelial replacement may be partial or total, complete or incomplete, and the resulting squamous epithelium may be mature or immature. The latter may be composed of squamous cells, showing **abnormalities of cell shape and, occasionally, nuclear enlargement**, when compared with normal. Some metaplastic cells may show **very large nuclei**, possibly the result of increased DNA, although there is currently no understanding of this observation. The **newly formed metaplastic epithelium very often retains some features of its predecessor**. For example, metaplastic squamous epithelial cells replacing mucus-producing endocervical epithelium may contain mucus.

In some organs and organ systems, for example in the bronchus, it is thought by some that squamous metaplasia of the bronchial epithelium may represent a steppingstone in the development of lung cancer. It is quite true that certain intraepithelial malignant lesions may resemble metaplasia, but the relationship of the two remains enigmatic. For further discussion of this important subject, see Chapter 20.

In human cytologic material derived from some organs, such as the endocervix or the bronchi, the presence of squamous metaplasia may be recognized under certain circumstances that will be described in the appropriate chapters.

The transformation of epithelial cells into cells known as **oncocytes (Hürthle cells)** may be observed in organs such as the salivary glands, thyroid, breast, and kidney. The oncocytes are rich in **mitochondria** that fill the cytoplasm. Such cells are characterized by unusual respiratory pathways and have been shown to have **abnormalities of mitochondrial DNA** (see Chap. 2). Virtually nothing is known about the mechanisms of their occurrence. The diagnostic significance of these cells will be discussed in the appropriate chapters.

Hyperplasia

The term *hyperplasia*, indicating **excessive growth**, may be applied to tissues or to individual cells. In light microscopy, the term is most often applied to an increase in the number of cell layers in a normally maturing epithelium (Fig. 6-12) or to an increase in the number of glandular structures, as in the endometrium. For whole organs, the term **hypertrophy** is used to indicate an increase in volume. For individual cells, the term must be used with great caution because it may indicate a benign process (as in cardiac muscle), but also a precancerous event or even cancer, when used in reference to epithelial cells. Unfortunately, in practice, these simple definitions are not always easy to follow. Quite often, the hyperplastic process is associated with abnormalities of component cells and the term **atypical hyperplasia** has been applied to such lesions. Atypical hyperplasia may pose significant diagnostic problems because the subsequent course of events cannot be predicted. Some of these lesions may regress or they may remain unchanged for many years. Other such lesions may progress to cancer if untreated (see Chaps. 11, 12, and 13).

Figure 6-12 Schematic presentation of events in epithelial hyperplasia and atrophy in squamous epithelium.

The recognition of hyperplasia in cytologic material is impossible unless the cells show notable abnormalities, as they may occur in the atypical variant.

Atrophy

Atrophy is the opposite of hyperplasia; it indicates a **reduction in the volume of an organ** or, in the microscopic sense, a reduction in the **number of cells within an organ or a tissue**, or a reduction in the size or volume of individual cells. In the practice of microscopy, the atrophy of certain tissues may be recognized. For example, the number of cell layers in a squamous epithelium may be reduced (see Fig. 6-13) or there may be a reduction in the size of the component cells of an organ. Sometimes, epithelial atrophy may be identified in cytologic material, for example, in smears from the female genital tract (see Chap. 8).

SPECIFIC NONNEOPLASTIC DISEASE PROCESSES AFFECTING CELLS

Inflammatory Disorders

Inflammation is a common form of **tissue reaction to injury**. The reaction is usually caused by **bacterial, viral, or fungal agents**, but it may also occur as a **response to tissue necrosis, foreign bodies, and injury by therapy**. The inflammatory processes always involve a **participation of the immune system**, which is represented at the site of reaction by polymorphonuclear leukocytes of various types, lymphocytes, plasma cells, and macrophages in various proportions, depending on the causes of the inflammatory reaction and its natural course. The recognition of the type of inflammation may help in assessing the type of injury to the participating cells. It is convenient to classify inflammatory reactions as acute, subacute, chronic, and granulomatous.

Acute Inflammation

The acute inflammatory-type response to injury is characterized by **necrosis** and breakdown of cells and tissues. Because of damage to capillaries and sometimes to larger blood vessels, **blood and blood products (fibrin)** are invariably present. The dominant inflammatory cells participating in this process are **neutrophilic polymorphonuclear leukocytes**, usually

accompanied by small populations of lymphocytes. The combination of necrotic material, cell debris, red blood cells, fibrin, and leukocytes, known collectively as **purulent exudate (pus)**, give a characteristic cytologic picture that is readily identified. Although the term “acute” for this inflammatory process suggests an event of short duration (and most of them are), some reactions of this type may persist for prolonged periods, sometimes lasting several years. The **outcome** of the acute inflammatory reaction is either **healing**, associated with **tissue regeneration** and repair of the damage, or a transition to a chronic inflammatory process.

Subacute Inflammation

Subacute inflammation is an infrequent variant of the acute inflammatory process, characterized by minimal necrosis of the affected tissues and the presence of **eosinophilic polymorphonuclear leukocytes** (eosinophils) and lymphocytes. Such reactions may also be observed in the presence of parasites, which appear to be able to mobilize eosinophils. There are no documented specific cell changes associated with this type of inflammatory reaction.

Chronic Inflammation

The chronic type of inflammation is, by far, the most interesting in diagnostic cytology because it **may cause perceptible cell changes**. As the name indicates, the reaction is usually of long duration. The dominant inflammatory cells are **lymphocytes, plasma cells, and macrophages**, which may be mononucleated or have multiple nuclei. Besides evidence of phagocytosis, the macrophages may show nuclear abnormalities in the form of nuclear enlargement and hyperchromasia. Rarely, **plasma cells** may be the dominant cell population, **especially in the nasopharynx and the oropharynx**; when this occurs, the possibility of a malignant tumor composed of plasma cells (multiple myeloma) must be ruled out. Epithelial cells and fibroblasts may show various manifestations of regeneration and repair, as discussed in the preceding pages.

Granulomatous Inflammation

Granulomatous inflammation is a form of chronic inflammation characterized by the formation of nodular collections (granules) of modified macrophages resembling epithelial cells, hence known as **epithelioid cells**. The epithelioid

P.141

cells are often accompanied by **multinucleated giant cells**, which have been shown to result from fusion of epithelioid cells (Mariano and Spector, see Chap. 4). The multinucleated cells observed in tuberculosis and related disorders are known as **Langhans' giant cells** (Fig. 6-13). Similar cells may occur as a reaction to foreign material and are then known as **foreign-body giant cells**. The causes of granulomatous inflammation have been recognized: infections with ***Mycobacterium tuberculosis*** and related acid-fast organisms and some species of fungi are most commonly observed. In AIDS, microorganisms that are not necessarily pathogenic in normal humans, may also cause this type of inflammatory reaction. For other examples of granulomatous inflammatory process, see Chapters 10, 19, and 29.

Figure 6-13 Tuberculosis of lymph nodes. Note several multinucleated giant cells (Langhans' cells) in the center of a spherical lesion composed of small epithelioid cells, forming a granuloma.

TABLE 6-1 CYTOPATHIC CHANGES CAUSED BY COMMON HUMAN VIRUSES

Virus	Cytoplasm	Nucleus	Inclusions
Herpesvirus (simplex of type 1 and type 2)	Enlarged in multinucleated cells	Early changes: ground-glass (opaque) nuclei, frequent multinucleation with nuclear Late stage: molding intranuclear inclusions	Eosinophilic intranuclear (in late stage)
Cytomegalovirus	May contain small satellite inclusions	Large inclusions with clear zones of "halos"	Mainly basophilic, sometimes eosinophilic large intranuclear inclusions with halos and smaller "satellite" inclusions in nucleus and cytoplasm
Human papillomavirus	Large, sharply demarcated perinuclear	Enlarged, sometimes pyknotic Virus documented	None

	clear zones due to cytoplasmic necrosis (koilocytes)	by immunologic techniques, electron microscopy, or DNA hybridization in situ	
Human polyomavirus	Normal or enlarged	Enlarged; chromatin replaced by a large inclusion (decoy cells)	Large, basophilic, homogeneous; no halo or satellite inclusion

RECOGNITION OF SPECIFIC INFECTIOUS AGENTS IN CYTOLOGIC MATERIAL

Inflammatory processes pertaining to various organs and organ systems will be discussed in appropriate chapters. Hence, this is but a brief overview of this field.

Bacteria

Very few bacterial agents cause specific cell changes, beyond the inflammatory reactions described above. Occasionally, however, specific microscopic images may be observed. Thus, the presence of the so-called **clue cells** in cervicovaginal smears is suggestive of an infection with *Gardnerella vaginalis* (see Chap. 10). *Chlamydia trachomatis* causes cell changes in the form of cytoplasmic inclusions. The cell changes in granulomatous inflammation, described above, occasionally may be observed in various cytologic preparations and in aspiration biopsy material.

Fungi

Fungal agents are easily identified by species in several diagnostic media. They are most commonly found, however, in pulmonary material, spinal fluid, and aspiration biopsies (see appropriate chapters for a description of these organisms).

Parasites

Parasitic agents are not commonly seen in the Western world, but are exceedingly common in the developing countries.

P.142

Several examples of parasites are given in the text (see appropriate chapters). The most important of these is the obligate intracellular parasite of uncertain classification,

Pneumocystis carinii, which is the cause of a pneumonia that occurs with high frequency in AIDS patients (see Chap. 19). Cytologic samples are commonly used for the identification of this agent.

Viruses

Viral agents may cause recognizable cell changes. A summary of the cytologic findings in infections with the most common viruses is provided in Table 6-1. Additional information is provided in chapters dealing with specific organs.

Therapeutic Agents

Radiotherapy, cryotherapy, and a number of drugs, most of them belonging to the group of cytotoxic chemotherapeutic agents, may cause significant cell abnormalities. Because of the diversity of these effects, which are organ related, the changes will be described in the appropriate chapters.

Fundamental Concepts of Neoplasia: Benign Tumors and Cancer

The term **neoplasia** (from Greek, *neo* = new and *plasis* = a moulding) indicates the formation of new tissue or a **tumor** (from Latin for swelling) that may be benign or malignant. The primary task of diagnostic cytology is the microscopic diagnosis and differential diagnosis of malignant tumors or cancers and their precursor lesions. This chapter presents an overview of these groups of diseases that will attempt to correlate current developments in basic research with a description of morphologic changes observed in tissues and cells.

BRIEF HISTORICAL OVERVIEW

Cancer has been recognized by ancient Greeks and Romans as **visible and palpable swellings or tumors**, affecting various parts of the human body. In fact, the very name of cancer (from Greek, *karkinos*, and Latin, *cancer* = crab) reflects the invasive properties of the tumors that spread into the adjacent tissues and grossly mimic the configuration of a crab and its legs. Ancient Greeks were even aware that the prognosis of a *karkinoma* (**carcinoma**) of the breast was poor but also cited alleged examples of healing the disease by amputation. Over many centuries, numerous attempts were made based on clinical and autopsy observations to separate “tumors” caused by benign disorders, such as inflammation, from those that inexorably progressed and killed the patient, or true cancers. These distinctions could not be objectively substantiated until the introduction of the microscope as a tool of research. As was narrated in Chapter 1, the first recognition of microscopic differences between malignant and benign cells is attributed to Johannes Müller (1836). Müller's work stimulated numerous investigators, including his student Rudolf Virchow, considered to be the founder of contemporary pathology, and led to the recognition of various forms of human cancer in the 19th century. The observations on microscopic makeup of cancer subsequently led to the recognition of precursor lesions

P.144

or precancerous states. The reader interested in the history of evolution of early human thoughts pertaining to cancer is referred to the books by M.B. Shimkin (1976), L.J. Rather (1978), and to the first chapter of this book.

In the first half of the 20th century, many attempts were made to shed light on the causes and sequence of events in cancer. Only a very few of these contributions can be mentioned here. As early as 1906, Boveri suggested that cancers are caused by chromosomal abnormalities. Differences in glucose metabolism between benign and cancerous cells were documented by Otto Warburg (1926), who believed that cancer was caused by insufficient oxygenation of cells or anoxia. Early measurements of cell components documented differences in nuclear and nucleolar sizes between benign and malignant lesions of the same organs (Haumeder, 1933; Schairer, 1935). The investigations of the sequence of events in experimental cancer supported

the concept of two stages of development—**initiation** and **promotion**. The principal contributors of this theory were Friedwald and Rous (1944) and Berenblum and his associates (summary in 1974) who documented that cancer of the skin in animals (usually rabbits) may be produced more efficiently if the target organ, treated with a carcinogenic agent (such as tar) was treated with a second, noncarcinogenic agent, acting as a promoter. Knudson (1971, 1976) proposed the “**two hit**” **theory of cancer**, in reference to retinoblastoma, a tumor of the eye. The theory assumed that two events may be necessary for this cancer to occur—a genetic error that may be either congenital or acquired, followed by another carcinogenic event that again could be either genetic or acquired. With the discovery that the **retinoblastoma gene** (Rb gene; see below) is damaged or absent in some patients with retinoblastoma, the theory has proved to be correct. Subsequent developments in molecular studies of cancer led to the discovery of numerous **tumor-promoting genes (oncogenes)** and **tumor suppressor genes**, discussed later. It has been documented within recent years that the transformation of normal cells into cancerous cells is a **multistep genetic process** that is extremely complex. It is virtually certain today that carcinogenesis in various organs may follow different and, perhaps, multiple pathways. So far, there are only a very few genetic abnormalities that may represent common denominators of several cancers, such as the **mutations of the p53 gene**, discussed later, but the events preceding these mutations are in most cases still hypothetical and obscure.

None of these observations has shed much light on the morphologic and behavioral differences between cancer cells and benign cells, which are the principal topics of this book. Nonetheless, there is no further doubt that **all tumors, whether benign or malignant, are genetic diseases of cells**.

BENIGN TUMORS

Definition

Benign tumors are **focal and limited proliferations of morphologically normal or nearly normal cells, except for their abnormal arrangement and quantity**. Benign tumors may occur in any tissue or organ and are characterized by:

- **Limited growth**
- **A connective tissue capsule**
- **The inability to either invade adjacent tissue or metastasize**

Classification

The most common benign tumors of epithelial origin are **papillomas**, usually derived from the squamous epithelium or its variants, such as the urothelium lining the lower urinary tract, and **adenomas** or **polyps**, derived from glandular epithelia (Fig. 7-1). Papillomas and polyps are visible to the eye of the examiner as pale or reddish protrusions from the surface of the epithelium of the affected organ. Microscopically, these tumors are characterized by a proliferation of epithelial cells, surrounding a core composed of connective tissue and capillary vessels. In some benign tumors of epithelial origin, such as **fibroadenomas of the breast**, the relationship of the epithelial structures and connective tissue is complex (see Chap. 29). Benign tumors **may also originate from any type of supportive tissue** (e.g., fat, muscle, bone) and usually **carry the name of the tissue of origin**, such as **lipoma, myoma, or osteoma** (Table 7-1).

Causes

The causes of benign tumors have not been fully elucidated but, in some of these tumors, **chromosomal abnormalities** have been observed (see Chap. 4 and Mitelman, 1991). The molecular significance of these abnormalities is not clear at this time. More importantly, Vogelstein and his group at Johns Hopkins observed that a **tumor suppressor gene named APC** (from **adenomatous polyposis coli**) is frequently mutated in benign polyps of patients with familial polyposis of colon, a disease characterized by innumerable colonic polyps and often leading to colon cancer. This gene

P.145

appears to **interfere with adhesion molecules maintaining the normal integrity of colonic epithelium**. The mutation of the APC gene may be a stepping stone to the development of colonic cancer (summary in Kinzer and Vogelstein, 1996). Although at this time no definitive information is available in reference to other benign tumors, it appears likely that they also occur as a consequence of mutations affecting genes essential in maintaining the normal relationship of cells.

Figure 7-1 Low-power view of rectal polyp. Note the central stalk of connective tissue and the benign glandular epithelium forming a mushroom around the stalk but also covering the stalk.

TABLE 7-1 CLASSIFICATION AND NOMENCLATURE OF HUMAN TUMORS*

Tissue Origin		Benign	Malignant (Cancer)
Stratified protective epithelium		Papilloma	Squamous or epidermoid carcinoma; urothelial carcinoma

Columnar epithelium, including that of glands	Adenoma or polyp	Adenocarcinoma, mucoepidermoid carcinoma Occasionally epidermoid carcinoma
Mesothelia Supportive tissues of mesodermal origin	Benign mesothelioma ...omas according to the type of tissue involved (i.e., fatlipoma, bone-osteoma)	Malignant mesothelioma Sarcoma (with designation of tissue type; i.e., liposarcoma, osteogenic sarcoma)
Lymphoid tissues	Hyperplasia	Malignant lymphomas
Blood cells		Leukemia
Tumors composed of several varieties of tissue	Benign teratomas	Malignant teratomas

*This simplified classification, although allowing a general orientation in tumor types, should not be taken too rigidly. A variety of malignant tumors may show a mixture of different types. Furthermore, combinations of sarcomas and carcinomas may occur. Special designations have been attached to a variety of benign and malignant neoplasms of some organs or systems. As the need arises, such diseases will be described in the text.

Another known cause of benign tumors is certain **viruses**. Thus, **papillomaviruses** may cause benign tumors in various species of animals. Certain types of the human papillomaviruses (HPVs) are the cause of benign skin and genital warts and papillomas of the larynx; other types, designated as “oncogenic,” are implicated in the genesis of cancer of the uterine cervix and other organs (see Chap. 11). It has been shown that some of the protein products, of the oncogenic types (which may also be involved in the formation of benign tumors), interact with protein products of genes controlling replication of DNA (p53) and the cell cycle (Rb) (see Chap. 11). No such information is available in reference to HPVs associated with benign tumors and the mechanisms of formation of warts remain an enigma at this time.

Cytologic Features

In general, **the cells of benign epithelial tumors differ little from normal**, although they may display evidence of proliferative activity in the form of mitotic figures. In general, the epithelial cells tend to **adhere well to each other** and form flat clusters of cells with clear cytoplasm and small nuclei, wherein cell borders are clearly recognized, resulting in the so-called **honeycomb effect** (Fig. 7-2).

Benign tumors of mesenchymal origin, such as tumors of fat (**lipomas**), smooth muscle

(**leiomyomas**), or connective tissue (**fibromas**), can be sampled only by needle aspiration biopsies. In smears, the **cell population resembles the normal cells of tissue of origin** (i.e., fat cells, smooth muscle cells, or fibroblasts). As a warning, some malignant tumors of the same derivation may be composed of cells that differ little from their benign counterpart (see Chap. 24).

However, some benign tumors, such as **tumors of endocrine**

P.146

or nerve origin, may show significant abnormalities in the form of large, hyperchromatic, sometimes multiple nuclei that explain why the DNA pattern of such tumors may be abnormal (Agarwal et al, 1991). In the presence of such abnormal cells, the cytologic diagnosis of benign tumors may be very difficult. Benign tumors caused by human papillomaviruses, such as skin warts and condylomas of the genital tract or bladder, may show significant cell abnormalities that may mimic cancer to perfection.

Figure 7-2 Cells from a benign epithelial tumor. In this example from prostatic hyperplasia, there is a flat sheet of cells of nearly identical sizes. The cell borders among cells are recognizable as thin lines, giving the “honeycomb” effect.

Benign tumors of many organs show specific microscopic features that may allow their precise recognition, as will be discussed in detail in appropriate chapters. On the other hand, in some organs, such as the endometrium, the distinction between benign proliferative processes, known as atypical hyperplasia, and low-grade cancer may depend on the preference of the observer (see Chap. 14).

Behavior

Some benign tumors may **regress spontaneously**, such as skin warts. However, most benign tumors do not regress but achieve a certain size and then either stop growing or continue to grow at a very slow rate. Still, the size alone may interfere with normal organ function and may require removal. Other reasons for therapy may be necrosis or hemorrhage within the benign tumor that may cause acute discomfort to the patient. Also, a **benign tumor may occasionally give rise to a malignant tumor** although, on the whole, this is a **rare event**. The mechanisms

and causes of such transformations are unknown, except for the colon, where it was shown, in high-risk populations, that a series of successive genetic abnormalities may lead from benign colonic polyps to cancer of the colon (see below).

MALIGNANT TUMORS (CANCERS)

Definition

Fully developed primary malignant tumors are characterized by several fundamental features that apply to all cancers:

- **Autonomous proliferation** of morphologically abnormal cells results in abnormal, often characteristic tissue patterns and leads to the formation of a visible or palpable swelling or tumor.
- **Invasive growth** involves growth of cancerous tissue beyond the boundaries of tissue of origin. The invasion may extend into adjacent tissues of the same organ and beyond.
- **Formation of metastases** involves growth of colonies of cancer cells in distant organs, which again can proliferate in an autonomous fashion. For metastases to occur, the cancer cells must have the ability to enter either the lymphatic or blood vessels. Spread of cancer through lymphatics is known as **lymphatic spread** and leads to metastases to lymph nodes. Spread of cancer through blood vessels is known as **hematogenous spread** and may result in metastases to any organ in the body, whether adjacent to the tumor or distant (see Chap. 43).

The terms **recurrent cancer** and **recurrence** indicate a relapse of a treated tumor.

Classification

Cancers originating from epithelial structures or glands are known as **carcinomas**, whereas cancers derived from tissues of middle embryonal layer origin (such as connective tissue, muscle, bone) are classified as **sarcomas**. The names of yet other cancers of highly specialized organs or tissues may reflect their origin, for example, **thymus = thymoma** and **mesothelium = mesothelioma**. Cancers of blood cells are known as **leukemias**, and cancers of the lymphatic system as **lymphomas** (see Table 7-1).

Carcinomas and sarcomas may be further classified according to the type of tissue of origin, which is often reflected in the component cells. Carcinomas derived from **squamous epithelium**, or showing features of this epithelial type, are classified as **squamous or epidermoid carcinomas**. In this text, the term “squamous carcinoma” will be applied to tumors with conspicuous keratin formation, whereas tumors with limited or no obvious keratin formation will be referred to as “epidermoid carcinomas.” Carcinomas derived from **gland-forming epithelium** or forming glands are classified as **adenocarcinomas**. There are also carcinomas that may combine the features of these two types of cancer and are, therefore, known as **adenosquamous** or **mucoepidermoid carcinomas**. Carcinomas of highly specialized organs may reflect the tissue of origin, for example, **hepatoma**, a tumor of liver cells.

Sarcomas are also classified according to the tissue of origin, such as **bone (osteosarcoma)**, **muscle (myosarcoma)**, and connective tissue or **fibroblasts (fibrosarcoma)**. Again, tumors derived from highly specialized tissues may carry the name of the tissue of origin, for example, **glial cells** of the central nervous system (**glioma**) or pigment-forming cells, melanoblasts (**melanomas**).

Yet other tumors may show **combinations of several tissue types (hamartomas and**

teratomas), or reflect certain common properties, such as production of hormones (**endocrine tumors**). In certain age groups, tumors that show similar morphologic characteristics (although not cells of origin) have been grouped together as **small-cell malignant tumors of childhood**. The feature of all these tumors will be discussed in appropriate chapters.

Immunocytochemistry may be of significant help in classifying tumors of uncertain origin or type (see below and Chap. 45).

Risk Factors and Geographic Distribution

Only about 5% of all malignant tumors occur in children and young adults. Most cancers are observed in people past

P.147

the age of 50. In fact, it can be stated that **advancing age is a risk factor for cancer**. The reasons for this are speculative and most likely are based on reduced ability of the older organism to control genetic abnormalities that are likely to occur throughout the life of an individual but are better controlled in the younger age groups. A possible candidate is capping of chromosomes by **telomeres** that protect the ends of chromosomes from injury and that are reduced with age (de Lange, 2001). Another important risk factor is **immunosuppression**, particularly in patients with AIDS (Frisch et al, 2001).

Epidemiologic data from various continents and countries suggest that **certain cancer types may preferentially occur in certain populations**. For example, gastric cancer is very common in the Japanese, whereas cancer of the nasopharynx and esophagus is common in the Chinese. On the other hand, prostatic cancer is much less frequent in Japan than in the United States, where the disease is particularly common among African-Americans. Such examples could be multiplied. Epidemiologic studies have attempted to identify the causes of such events with modest success. It is known, for example, that among the Japanese living in Hawaii and the mainland United States, the rate of gastric carcinoma drops rapidly, and the change is attributed to a different diet. Several other environmental risk factors have been identified, but there are still huge gaps in our understanding of these events. The search for factors that may account for the geographic disparities is still in progress.

Causes

The first observations on the causes of human cancer had to do with **environmental factors**. Thus, an epidemic of lung cancer was observed in the 1880s in Bohemia (today the Czech Republic) in miners extracting tar that was subsequently shown to be radioactive (see Chap. 20). In the 1890s, after the onset of industrial production of organic chemicals, some chemicals were shown to cause bladder tumors (see Chap. 23). Asbestos has been linked with malignant tumors of the serous membranes (mesotheliomas; see Chap. 26), cigarette smoking with lung cancer, and exposure to ultraviolet radiation with skin cancers and melanomas. Many of these relationships have been studied by **cancer epidemiology**, a science that attempts to document in an objective, statistically valid fashion the relationship of various factors to cancer.

Another association of cancer is with infectious agents, such as **viruses** and **bacteria** (Parsonnet, 1999). Several **RNA viruses**, today known as retroviruses, have been shown to cause malignant tumors and leukemias in mice and other rodents, among them mammary carcinoma (Bittner, 1947; Porter and Thompson, 1948) and erythroleukemia in mice (de Harven, 1962). The ability of certain **DNA viruses**, such as the simian virus 40 (SV 40), to modify the features and the behavior of cells in culture has also been documented (Dulbecco, 1964). Such modified cells, when injected into the experimental animal, produce tumors capable of metastases.

In humans, a number of **DNA viruses** have been implicated in various malignant processes. As previously mentioned, **human papillomaviruses (HPVs)** of certain types have been linked with cancer of the uterine cervix (see Chap. 11) and the esophagus (see Chap. 24). Another DNA virus, the **Epstein-Barr virus (EB virus)** was implicated in Burkitt's lymphoma and nasopharyngeal carcinoma. **Virus of hepatitis B** has been implicated in malignant tumors of the liver (hepatomas), whereas a newly discovered **herpes virus type 8** has been found in association with vascular tumors, known as Kaposi's sarcoma, and certain types of malignant lymphomas in patients with AIDS.

Bacteria, notably ***Helicobacter pylori***, have now been implicated in the origin of **gastric carcinoma** and, perhaps, the uncommon **gastrointestinal stromal tumors (GISTs)** (see Chap. 24).

However, **the vast majority of human cancers occur in the absence of any known risk factors**. With the onset of molecular biology, the study of members of families with known high risk for certain cancers (**cancer syndromes**; see below) has led to the observations that they carried certain genetic abnormalities that were either recessive or dominant. These abnormalities have led to the studies of molecular underpinning of the events leading to cancer, discussed below.

Grading and Staging

Grading of cancers is a subjective method of analysis of cancers that attempts to describe the histologic (and sometimes cytologic) **level of deviation from normal tissue or cells of origin. Grading is expressed in Roman numbers or equivalent phrases**. If the histologic pattern of a cancer resembles closely the makeup of the normal tissue, and is composed of cells that closely resemble normal, it may be graded as **well differentiated**, or **grade I**. On the other extreme are cancers that barely resemble the tissue of origin, if at all, and are composed of cells that differ significantly from normal; such cancers can be classified as **poorly differentiated**, or **grade III**. Most cancers fall somewhere between the two extremes and are therefore classified as **moderately well differentiated**, or **grade II**. There are also systems of **grading based exclusively on the configuration of nuclei of cancer cells**, particularly in breast cancer (see Chap. 29). Several objective methods of measurements of cancer cells and their nuclei have been introduced to replace subjective grading (review in Koss, 1982). Grading may have some bearing on behavior of cancer, inasmuch as poorly differentiated tumors may be more aggressive than well differentiated. Grading is most valuable as a modifier of cancer staging.

Staging of cancers is based on an internationally accepted code **to assess the spread of cancer at the time of diagnosis. The TNM system** includes tumor size and extent of invasion (**T**), the involvement of the regional lymph nodes by metastases (**N**), and the presence or absence of distant metastases (**M**). The **T** group is usually subclassified and ranges from Tis (tumor in situ) or To, indicating a cancer confined to the tissue or organ of origin, to T1, T2,

P.148

T3 and T4, indicating tumor size and, in some instances, the depth of invasion.

Clinical staging is based on the results of inspection and palpation, now usually supplemented by radiologic techniques, such as magnetic resonance imaging (MRI) or ultrasound. **Pathologic staging** is based on examination of tissues surgically removed from the patient. The pathologic stage of a tumor may be higher than the clinical stage because, on microscopic examination, spread of cancer may be discovered in tissues that were clinically not suspect of harboring disease. **The TNM system (sometimes combined with grading) is particularly useful in**

assessing the prognosis. T1 tumors have a much better outcome than T3 or T4 tumors. Tumors without metastases have a better prognosis than tumors with metastases. The TNM system is very useful in comparing the results of treatment of various malignant diseases in different institutions.

Behavior

In principle, all invasive cancers, if untreated, should lead to the death of the patient. However, even in untreated patients, **the behavior of cancers may be extremely variable**; some types of malignant tumors progress very slowly and take many years to spread beyond the site of origin, whereas other cancers progress and metastasize very rapidly, such as some cancers composed of small, primitive cells. In experimental systems, arrest and regression of malignant tumors was accomplished by a variety of manipulations (e.g., Silagy and Bruce, 1970) or by replacement of damaged genes and chromosomes. There is no doubt that occasionally, but very rarely, a **spontaneous regression** of human cancer can occur. Gene replacement therapy, however, has not been successful to date in human cancer.

Although **statistical data** are available today in reference to **prognosis** of most tumor types, experience shows that the **rules do not always apply to individual patients**. Except for the recognition of some cancer types with notoriously rapid progression, the classification of tumors by histologic (or cytologic) types may have limited bearing on behavior that is sometimes dependent on the organ of origin. For example, patients with squamous carcinomas of the cervix have a generally better prognosis and live longer than patients with cancers of identical type of the esophagus. As a group, adenocarcinomas of the breast are likely to be more aggressive and produce metastases sooner and more frequently than adenocarcinomas of the endometrium. In most common cancers, the behavior is better correlated with tumor stage than histologic type or grade, although grading may be a modifier of staging. The behavior of tumors of the same stage but different grades may vary. Tumors of higher grade often behave in a more aggressive fashion.

PRECURSOR LESIONS OF HUMAN CANCER

Although the concepts of precursor lesions of cancers were proposed in the early years of the 20th century (see Chap. 1), the existence and significance of these processes was firmly established during the last half of the 20th century. It is now known, with certainty, that **tumors of epithelial tissue origin or carcinomas are preceded by abnormalities confined to the epithelium** (Fig. 7-3). All these precursor lesions were initially classified as **carcinoma in situ**, and are now subdivided into several categories with names such as **dysplasia** or **intraepithelial neoplasia**. **Some of these lesions may be graded** by numbers (grade I, II, or III); by

P.149

adjectives, such as “mild,” “moderate,” or “severe”; or, within recent years, as “**low-grade**” or “**high-grade**” lesions. The **grading** has been used to indicate the makeup of these lesions—that is, the **degree of morphologic abnormality**—when compared with normal tissue of origin. Lesions resembling closely the epithelium of origin, albeit composed of abnormal cells, are classified as “low grade.” Lesions showing less or little resemblance to the epithelium of origin, usually composed of small abnormal cells, are classified as “high grade.” The grading has some bearing on the behavior of the precursor lesions, although in practice it has a rather **limited value and reproducibility**, as will be set forth in appropriate chapters.

Figure 7-3 Carcinoma in situ (severe dysplasia) of colon. *A*. Low power view of normal (*right*) and abnormal (*left*) colonic epithelium. *B, C*. The differences between the makeup of benign glands (*B*) lined by mucus-producing cells with small nuclei, and the malignant epithelium (*C*) composed of cells with no secretory function, very large nuclei, and evidence of mitotic activity are shown.

The **general characteristics of precursor lesions of carcinomas** are as follows:

- **The lesions are confined to the epithelium of origin.**
- **They are composed of** cells showing abnormalities that are similar but not necessarily identical to fully developed cancers.
- **Their discovery is usually the result of a systematic search**, usually by cytologic techniques (e.g., in the uterine cervix, lung, oral cavity, urinary bladder, or esophagus) or incidental biopsies (e.g., colon). Although some precursor lesions may produce clinical abnormalities visible to the eye, such as redness, they do not form visible tumors. The discovery of precursor lesions is one of the main tasks of diagnostic cytology.

- **The behavior of precancerous lesions is unpredictable.** Some of these lesions are capable of progression to invasive cancer but the likelihood of **progression varies significantly from organ to organ**. For example, in the urinary bladder at least 70% to 80% of untreated precursor lesions (flat carcinomas in situ and related lesions) will progress to invasive cancer, whereas, in the uterine cervix, the likelihood of progression does not exceed 20% (see Chaps. 11 and 23). The data for other organs are not secure because the system of discovery of precancerous lesions is not efficient. It must be noted that molecular genetic studies of precancerous lesions of the urinary bladder disclosed the presence of abnormalities that may also be observed in fully developed cancer. Similar observations were made in the sequence of events leading to cancer of the colon.

Progression of Intraepithelial Lesions to Invasive Cancer

Epidemiologic studies have shown that, as a general rule, precursor lesions occur in persons several years younger than persons with invasive cancer of the same type. Hence, it is assumed that **several years are required for an intraepithelial lesion to progress to invasive cancer**. For invasion to take place, the cells of the precursor lesion must break through the barrier separating the epithelium from the underlying connective tissue and, hence, **must breach the basement membrane**. One of two possible events must be assumed:

- The cells composing the precancerous lesions acquire new characteristics that allow them to breach the basement membrane.
- The basement membrane becomes altered and becomes a porous barrier to the cells.

Although the molecular mechanisms of such events are unknown at this time, there is evidence that some of the genes involved in carcinogenesis affect the adhesion molecules on cell membranes (see below). This relationship, when unraveled, may explain the mechanisms of invasion. Another, as yet unexplored, possibility is that the **basement membrane is breached by ingrowing or outgrowing capillary vessels**, thus paving the way for cancer cells to escape their confinement.

CURRENT TRENDS IN MOLECULAR BIOLOGY OF HUMAN CANCERS

Overview of the Problem

Cancer is a disease of cells that escape the control mechanisms of orderly cell growth and acquire the ability to proliferate, invade normal tissues, and metastasize. It is generally assumed that cancer is a **clonal disorder derived** from a single transformed cell (see below). The fundamental research issue was to determine whether cancer was the result of stimulation of cell growth, damage to the mechanisms regulating normal cell replication, or both. Marx (1986) referred to this dilemma as the Yin and Yang of cell growth control, referring to the old Chinese concept of contradictory forces in nature.

There were several significant problems with the study of molecular events in cancer. One of them was the **heterogeneity of cancer cells**—the observation that few, if any, cancer cells were identical. This phenomenon of cancer cell diversity was extensively studied by Fidler et al (1982, 1985), who documented that, in experimental tumors in mice, some cancer cells were capable of forming metastases and others were not. It has also been known for several years that the number and type of chromosomal abnormalities increased with the progression of cancer, reflecting the genomic instability in the cancer cells (recent review in Kiberts and Marx, 2002). Nowell (1976), who studied this phenomenon in leukemia, called it **clonal evolution**. In cytogenetic studies of fully developed solid cancers, the number of chromosomes in individual

cancer cells is often variable and other aberrations of chromosomes may also occur (see Chap. 4). It is not an exaggeration to state that advanced human cancer represents a **state of genetic chaos**. The diversity of cancer cells, even within the same tumor, made it very difficult to assess whether observed molecular genetic abnormalities had universal significance or were merely an incidental single event (recent reviews in Tomlison et al, 2000, and Hahn and Weinberg, 2002).

The type of material that was available to the basic science investigators also posed similar problems. Fragments of cancerous tissues available for such purposes were usually derived from advanced tumors that were likely to show a great deal of heterogeneity and genetic disarray. In vitro

culture of human cancers is technically difficult, and the cell lines derived therefrom usually represented a single clone of cells that is not necessarily representative of the primary tumor.

Further complications arose when DNA or RNA were extracted from such tissue samples for molecular analysis. Besides tumor cells, such tissues always contained an admixture of benign cells from blood vessels, connective tissue stroma, inflammatory cells, and remnants of the normal organ of origin. The question as to what constituted tumorspecific findings, rather than findings attributable to normal cells, was often difficult to resolve. Many of these difficulties persist.

Some solutions to these dilemmas came from several unrelated sources. One of them was the discovery of **growthpromoting DNA sequences**, known as **oncogenes**, and their precursor molecules, the **protooncogenes**, in an experimental system of transformed rodent cells. The protooncogenes and oncogenes could be isolated and sequenced. The search could now begin for matching sequences in the DNA extracted from normal human tissues and cancer. The protooncogenes and oncogenes and their role in cancer are described below.

Another breakthrough occurred with the study of the patterns of occurrence of **retinoblastoma**, an uncommon malignant tumor of the retina in children. Knudson (1971) anticipated that a fundamental genetic abnormality accounted for the familial pattern of this disease. This abnormality was subsequently identified as a deficiency or absence of a gene located on chromosome 13, which was named the **retinoblastoma (Rb) gene** (see below for further discussion). Similar studies of **families with “cancer syndromes”** were also conducted. Such families, described by a number of investigators (Gardner, 1962; Li and Fraumeni, 1969; summaries in Lynch and Lynch, 1993; Fearon, 1997; Varley et al, 1997; Frank 2001) were characterized by a high frequency of occurrence of cancers in various organs. The most important cancer syndromes are listed in Table 7-2. By a variety of techniques known as **linkage analysis**, the genetic abnormalities could be identified and the genes localized—first to chromosomes, then to segments of chromosomes, and, finally, to the specific location on the affected chromosome. The isolation and sequencing of such genes were an essential step in studying their function and interaction with other genes.

TABLE 7-2 MOLECULAR GENETICS OF SOME CANCER SYNDROMES PERTINENT TO DIAGNOSTIC CYTOLOGY

Syndrome	Tumor Suppressor Gene	Chromosomal Location	Clinical Significance —Target Organs	Cytologic Targets
----------	-----------------------	----------------------	--------------------------------------	-------------------

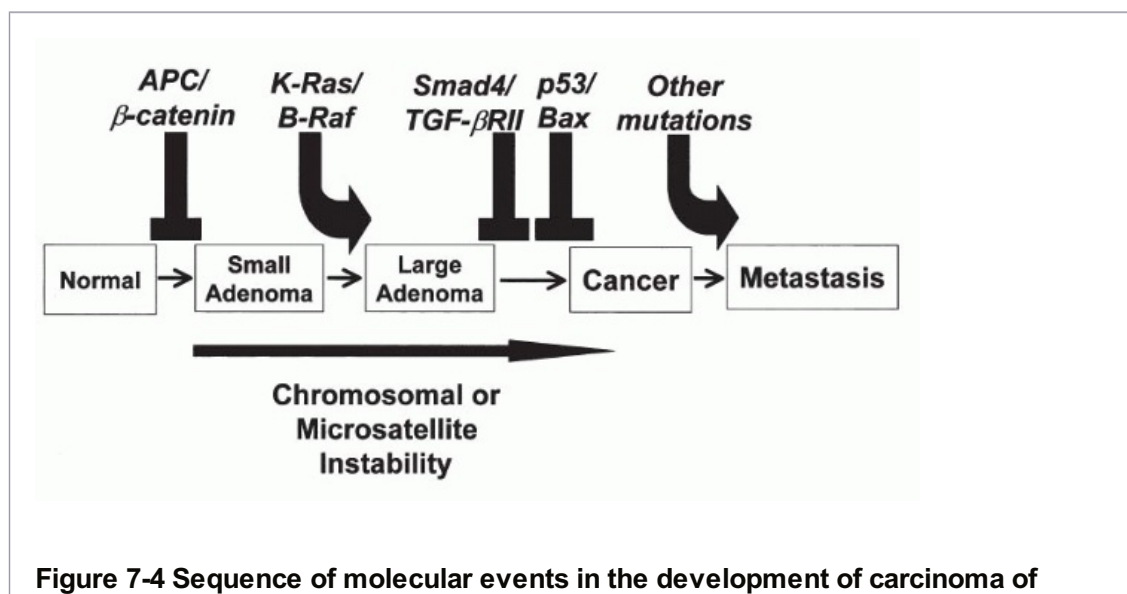

Familial polyposis coli	APC	5 q	colon cancer	metastatic cancer (liver, effusions, etc.)
Hereditary retinoblastoma	RB 1	13 q	eye: retinoblastoma bone: osteosarcoma	primary or metastatic
Breast cancer (less commonly ovarian and tubal cancer)	BRCA 1	17 q	breast, ovary	primary or metastatic
	BRCA 2	13 p	breast, pancreas	primary or metastatic
Li-Fraumeni	p53	17 p	diverse malignant tumors	primary or metastatic
Multiple endocrine neoplasia (MEN 1)	MEN 1	11 q	tumors of endocrine organs [thyroid, parathyroid, adrenal, pancreas (islands of Langerhans), pituitary]	primary or metastatic
Multiple endocrine neoplasia (MEN 2)	RET [*]	10 q	thyroid: medullary carcinoma,	primary or metastatic
	adrenal: pheochromocytoma			
Renal ca (part of von Hippel-Lindau syndrome)	VHL	3 p	kidney: carcinoma	primary or metastatic
Wilms' tumor	WT 1	11 p	kidney: Wilms' tumor	primary or metastatic
Peutz-Jeghers	STK 11 ⁺	19 p	associated with	endocervical

syndrome			minimal deviation endocervical adenocarcinoma	adenocarcinoma
Hereditary melanoma	P16	9 q	skin: malignant melanoma	metastatic tumors
	CDK4	12 q		
<p>* oncogene q = long arm of chromosome</p> <p>+ inactivation of protein kinases p = short arm of chromosome</p>				

Of special value in this research were **families with congenital polyposis of the colon**, a disease process in which the patients develop innumerable benign colonic polyps and, unless treated, invasive cancer of the colon sooner or later. A group at The Johns Hopkins medical institutions in Baltimore, MD, led by Vogelstein, Fearon, and others, undertook a systematic study of genetic changes occurring

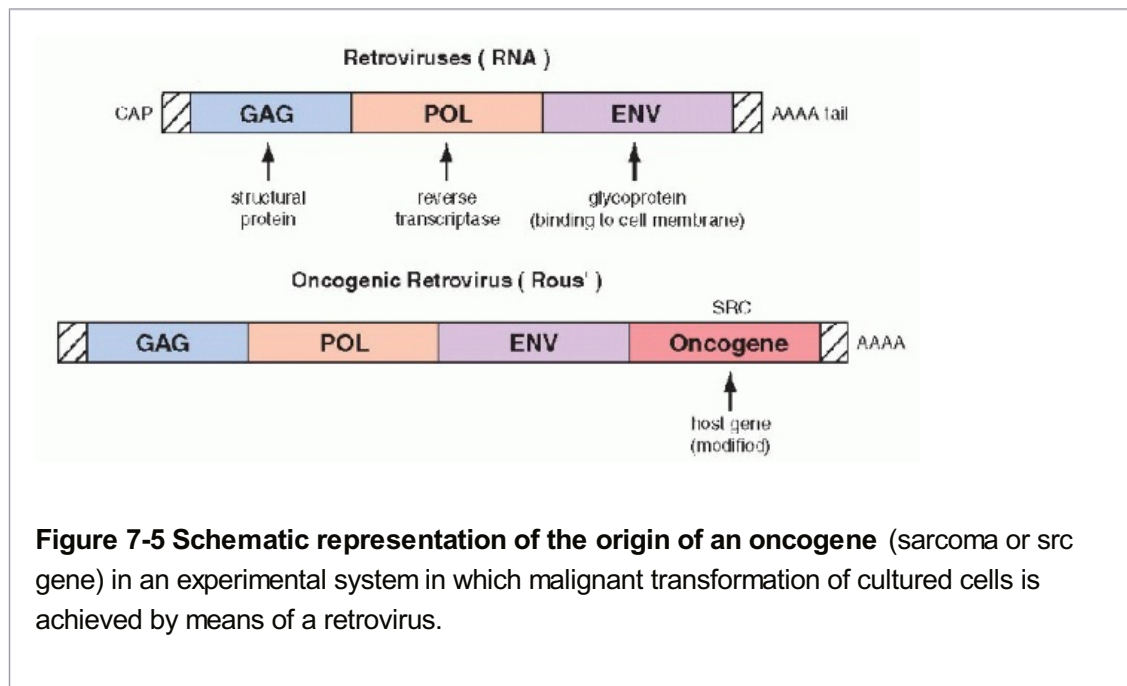

P.151

in benign colonic polyps, polyps with atypical features, early cancer, and invasive colonic cancer. These studies led to a **model of carcinogenesis** in the colon that postulated a sequence of genetic abnormalities leading from normal epithelium to polyps to cancer (Fig. 7-4). Although this model is not likely to be applicable to all cancers of the colon, let alone other organs, it stimulated a great deal of research on carcinogenesis. Perhaps the most important developments, resulting directly or indirectly from the studies of familial cancer, were the discovery of the role played by regulatory genes (**tumor suppressor genes**) in the events of **cell cycle** and the **relationship of genes involved in cancer genesis with adhesion molecules** that regulate the relationship of cells to each other and to the underlying stroma. These observations are discussed below.

colon. (Courtesy of Dr. Bert Vogelstein, Johns Hopkins Medical Institutions, Baltimore, MD.)

Another development that proved to be of significance in this research was the **Human Genome Project**, which provided a great deal of information on the distribution of genes on human chromosomes. Although the map of the human genome has been completed and the significance and role played by most of the genes remain unknown, commercial probes to many of these genes have become available that allow the study of genetic abnormalities in various human cancers. The emerging information is, unfortunately, enormously complex and so far has shed little light on the initial events, or sequence of events, in solid human cancer. Still, the genome project led to the discovery of the human breast cancer genes BRCA1 and BRCA2, to be discussed below.

Protooncogenes and Oncogenes

The first significant observation shedding light on the molecular mechanisms of cancer was the discovery of **oncogenes** in the 1980s (summary in Bishop, 1987). The oncogenes were first identified in experimental systems in which cultured, benign rodent cells were infected with **oncogenic RNA viruses (retroviruses)** and were transformed into cells with malignant features. The viral RNA, by means of the enzyme reverse transcriptase is capable of producing cDNA that is incorporated into the native DNA (genome) of the cell, which becomes the source of viral replication. It has been observed that **regulatory genes of host DNA, named protooncogenes**, which may be incidentally appropriated by the viral genome, **are essential in the transformation of the infected cells into cells with malignant features**. The “stolen” **host cell genes**, when either **overexpressed or modified** (mutated), **become a growth-promoting factor that has been named an oncogene** (Fig. 7-5). The first oncogenes discovered were named ***ras*** (retrovirus-associated sarcoma or **rat sarcoma**). Several variants of the ***ras*** oncogenes were subsequently discovered and described with various prefixes, such as ***Ki-ras***, ***Ha-ras***, and ***N-ras***, reflecting the initials of the investigators.

Shortly after the discovery of the first protooncogenes and oncogenes and their sequencing, their presence could be documented by Southern blotting and similar techniques in DNA from

normal human tissues, in human tumors, and in cell lines derived therefrom. On the assumption that the study of oncogenes will provide the clue to the secrets

P.152

of abnormal cell proliferation in cancer, the search for other oncogenes and growth-promoting factors began in earnest and led to the discovery of a large number of such genes that have now been sequenced and traced to their chromosomal sites.

Two fundamental modes of oncogene function have been identified—**overexpression (amplification)** of a normal protooncogene product, and a **point mutation**, a single nucleotide change in an exon of the gene, leading to a modified protein product. It is known that some oncogenes can be activated because their original chromosomal site has been disturbed by breakage and **translocation of chromosomal segments**, as observed in lymphomas and leukemias (see below). They may also be overexpressed in chromosomal fragments, such as C-**myc** oncogene, observed in the **double-minute chromosomes** of neuroblastoma (see Chap. 4).

The protooncogenes and the oncogenes exercise their activity **through their protein products**, many of which have been identified. For example, the genes of the **ras** family encode a group of proteins of 21,000 daltons, known as p21. Contrary to the initial hopes that all oncogenes would have a simple, well-defined function in the transformation of benign into malignant cells, it is now evident that the oncogenes are a diverse family of genes, with different locations within the cell and different functions. Several oncogenes have been traced to the nucleus (e.g., **myc, myb, fos, jun**), presumably interacting directly with DNA. Other proteins encoded by oncogenes have an affinity for cell membranes (e.g., **ras, src, neu**) or the cytoplasm (e.g., **mos**). These latter two groups of oncogenes appear to interact, on the one hand, with cytoplasmic and cell membrane receptors and, on the other hand, with enzymes, such as tyrosine kinase, that play a role in DNA replication. It is possible that the oncogenes located on cell membranes are instrumental in capturing circulating growth factors that stimulate proliferation of cells.

In **solid human tumors**, the activation or overexpression of various oncogenes has been shown to be a **common event**, unlikely to establish a simple cause-effect relationship between oncogene activation and the occurrence of human cancer. The presence of oncogene products could be demonstrated either by molecular biology techniques or by immunocytochemistry in many different human cancers. As an example, the presence of the **ras** oncogene product, p21, has been documented by us and others in gastric, colonic, and mammary cancer cells, and in several other human tumors (Czerniak et al, 1989, 1990, 1992). In cytochemical studies, it was noted that oncogene products are **variably expressed by cancer cells**, some of which stain strongly and some that do not stain at all, suggesting heterogeneity of oncogene expression. It is possible that the expression of the oncogene products is, to some extent, cell cycle dependent (Czerniak et al, 1987). With image analysis and flow cytometric techniques (see Chaps. 46 and 47), the amount of the reaction product can be measured (Fig. 7-6). Press et al (1993) stressed that immunocytologic microscopic techniques with specific antibodies are probably more reliable in assessing the expression of an oncogene in tissues than is the Southern or northern blotting technique. The blotting techniques require the destruction of the tissue samples and, therefore, fail to provide information on the makeup of the destroyed tissue and on the proportion of normal cells in the sample.

However, there is no agreement on the diagnostic or prognostic value of such measurements in human solid tumors, with a few exceptions. For example, the elevated expression of the product of the **oncogene HER2** (also known as **c-erbB2**), a transmembrane receptor protein, indicates

poor prognosis and rapid progression of breast cancers in about 25% of affected women (Slamon et al, 1989). In fact, an **antibody to the protein product of this gene** has been developed commercially for human use and is of benefit in prolonging life in some women with advanced metastatic breast cancer (see Chap. 29). This is one of the first indications that knowledge of the oncogenes or tumorpromoting factors may be of benefit to patients. Although oncogenes play an important role in human cancer, their precise role is complex (summary in Krontiris, 1995). Weinstein (2002) suggested that individual cancers are “addicted” to their specific oncogenes and suggested that oncogene suppression may lead to cure.

As an example, the drug Gleevec (Novartis) has been shown to be effective against chronic myelogenous leukemia by blocking the oncogenic protein **bcr = abl**, the product of chromosome translocation.

Tumor Suppressor Genes and Gatekeeper Genes

The oncogene story became even more complicated with the identification of genes known collectively as tumor suppressor genes or gatekeeper genes. As previously mentioned, this research has been stimulated by studies of **families with cancer syndromes** (recent summary in Fearon, 1997; see Table 7-2). The first such gene discovered was the **retinoblastoma (Rb) gene**, located on the short arm of chromosome 13. Retinoblastoma is an uncommon, highly malignant eye tumor of childhood that occurs in two forms: (1) a familial form, in which usually both eyes are affected, and (2) a sporadic form, in which one eye is affected. Following treatment of retinoblastoma, other cancers, such as osteogenic sarcoma, may develop in the affected children. Thus, the defect of the Rb gene may have multiple manifestations.

It was postulated by Knudson in 1971 that retinoblastomas are the consequence of two mutational events (**two-hit theory of cancer**). The familial form of retinoblastoma implied a hereditary defect of some sort, supplemented by a single additional sporadic mutation, leading to cancer. In the sporadic form, two mutational events were anticipated against a normal genetic background. In retinoblastoma, the gene on chromosome 13 was frequently deficient or absent, thus fulfilling the first requirement of Knudson's hypothesis. This gene has now been sequenced and its anti-tumor activity has been confirmed in vitro by Huang et al in 1988. It has been learned in recent years that the protein **product of the Rb gene regulates the expression** of one of the proteins regulating the cell cycle, known as **D cyclins**, which govern the transition of cells from G₀ to G₁ stage of

P.153

mitosis. It is postulated that **the absence of, or damage to, the Rb gene deregulates the cell cycle, leading to cancer.**

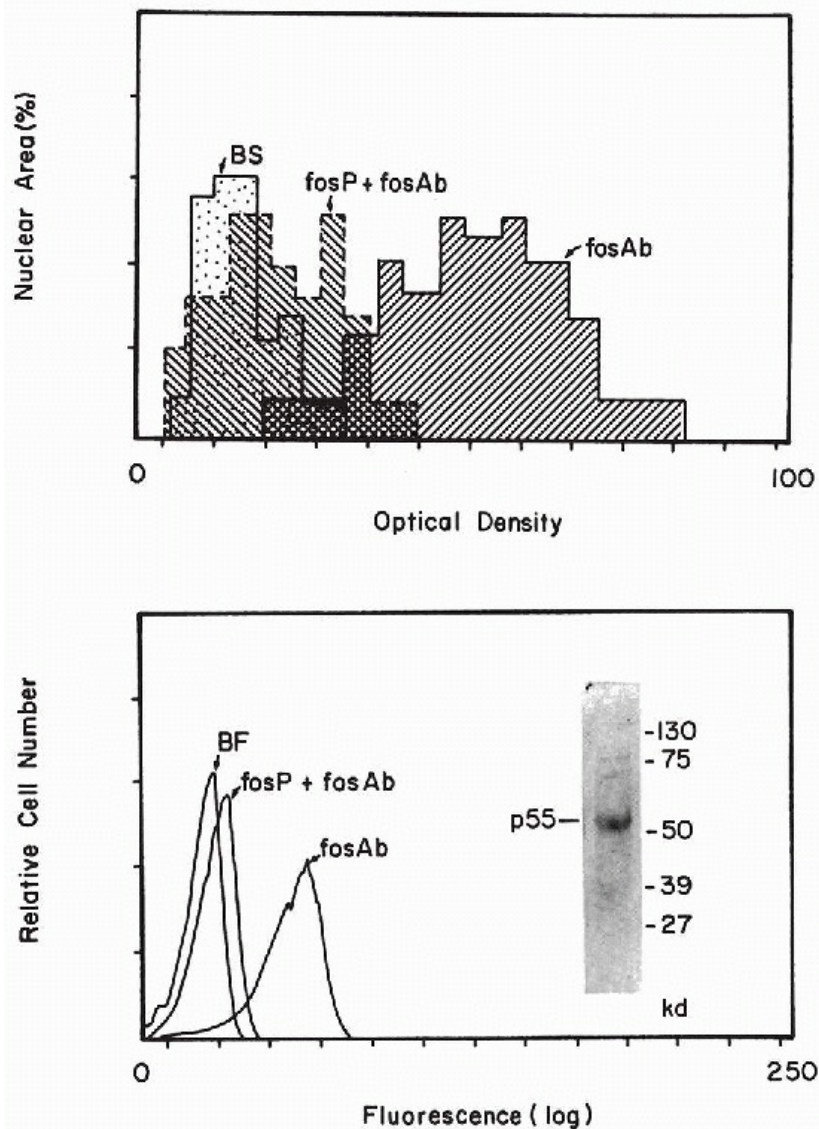

Figure 7-6 Measurement of *fos* p55 by computer-assisted image analysis (*top*) and flow cytometry (*bottom*). BS = background staining; *fosP* + *fosAb* = antibody to *fos* product p55 blocked by p55; *fosAb* = expression of unopposed antibody to p55; BF = background fluorescence. (*Bottom right*) Western blot of MCF7-KO protein extract incubated with antibody to *c-fos* p55. (Czerniak B, et al. Quantitation of oncogene products by computer-assisted image analysis and flow cytometry. *J Histochem Cytochem* 38:463, 1990.)

Another important regulatory gene is **p53**, a protein product of the gene located on the short arm of the chromosome 17 (Levine et al, 1991). p53 is a DNA binding protein that **regulates the transcription of DNA, its repair** by a cascade of other proteins, and is, therefore, considered to be a “**guardian of the genome**” (Lane, 1992). If a transcriptional error occurs, the replication is stopped until the error is repaired. The mechanism of arrest is mediated by a cell cycle inhibitor, protein p21^{WAF1/CIP1}, which is different from the p21 protein of the *ras* gene. If the repair is not executed, the cell may enter into the cycle of programmed cell death or **apoptosis**, discussed in detail in Chapter 6.

The natural p53 product is short-lived and difficult to demonstrate; however, a gene mutation

leads to a modified protein that has a much longer life span and can be demonstrated by a variety of techniques, including immunocytochemistry. **Loss of heterozygosity of p53** (inactivation or mutation of one of the two identical genes within the cell) is a very **common event** in many human cancers of various organs, mainly in advanced stages (see later text). However, in some cancers, such as high-grade cancer of the endometrium, the mutation of p53 is presumed to occur as an early event (see Chap. 13). The presence of mutations of the Rb gene and of the p53 protein has been shown to confer a poor prognosis on some cancers, such as cancers of the bladder (Esrig et al, 1993; Sarkis et al, 1993), some malignant lymphomas (Ichikawa et al, 1997), and chondrosarcomas (Oshiro et al, 1998).

Other tumor suppressor genes include the recently identified **breast cancer genes, BRCA1 and BRCA2** (see Table 7-2). The mutations of these genes have been observed in a larger proportion of Jewesses of Eastern European (Ashkenazi) origin than in other comparable groups of women (recent summary in Hofmann and Schlag, 2000). Although some of these women are at an increased risk for breast, and, to a lesser extent, ovarian and tubal cancer, and deserve close follow-up, the extent of risk for any individual patient cannot be assessed. In some of these women, preventive measures, such as a prophylactic mastectomy and oophorectomy have been proposed (Schrag et al, 1997). Clearly, many such dilemmas will occur as new risk factors for cancer are discovered. Silencing of tumor suppressor genes may be caused by **methylation** that does not involve DNA mutations (recent summary in Herman and Baylin, 2003).

P.154

Another set of genes involved in malignant transformation of normal cells into cancer cells is the **susceptibility genes**, considered by Kinzer and Vogelstein (1998) as “**caretakers of the genome**.” These genes, when mutated or inactivated, contribute indirectly to the neoplastic process, probably by regulating the relationship of the transformed cells to connective tissue stroma. Such genes have been observed in a colon cancer syndrome known as the **hereditary nonpolyposis colorectal cancer** (summary in Kinzer and Vogelstein, 1996). These observations bring into focus another critical issue in reference to cancer, namely **the relationship of cancer cells to adhesion molecules** that normally maintain order within the tissue and are critical in understanding the mechanism of cancer invasion and metastases. Several such molecules, such as **cadherins** (Takichi, 1991), **integrins** (Albelda, 1993), **lamins** (Liotta et al, 1984), and **CD44** (Tarin, 1993), have been studied and have been shown to be of significance in cancer invasion and metastases.

It is the consensus of most investigators that cancer is a **multistep process** that includes **sequential and progressive accumulation of oncogenes and inactivation of growth-regulating genes**.

Microsatellite Instability

Another **mechanism of cancer formation** is instability of microsatellites, which are repetitive DNA sequences scattered throughout the genome. It has been noted that about 15% of colon cancers with a relatively normal chromosomal component display abnormalities of microsatellites (Gryfe et al, 2000; de la Chapelle, 2003). It is of note that the **two pathways of colon cancer**, i.e., chromosomal instability and microsatellite instability, result in different tumors with different behavior pattern and prognosis. The tumors with **chromosomal instability** are aneuploid, occur mainly in descending colon, and have a poor prognosis when compared with tumors with **microsatellite instability**, which tend to be diploid and occurring mainly in ascending colon (de la Chapelle, 2003).

Gene Rearrangement in Malignant Lymphomas and Leukemias: Effects of Translocations

Chromosomal abnormalities in leukemias have been studied since the onset of contemporary genetics. The **Philadelphia chromosome** (Ph), a shortened chromosome 22, described by Nowell and Hungerford in 1960 in chronic myelogenous leukemia, was the first documented chromosomal abnormality characteristic of any human cancer (see Chap. 4). With the availability of the techniques of chromosomal banding and molecular biology, the genetic changes in this group of diseases could be studied further. Many of these fundamental observations are of diagnostic and prognostic value. In many disease processes within this group of cancers, an **exchange of chromosomal segments** or **translocation** is observed (see Chap. 4 for a discussion of cytogenetic changes in human cancer). Thus, it has been shown that the Ph chromosome is the result of a translocation of portions of the long arm of chromosome 22 to the long arm of chromosome 9 [abbreviated as t(9;q22)]. In certain forms of malignant lymphoma (notably in lymphomas of Burkitt's type), there is a reciprocal translocation between segments of chromosomes 14 and 18 (Fig. 7-7).

Figure 7-7 Reciprocal translocation between fragments of chromosomes 8 and 14 in Burkitt's lymphoma. The translation activates the myc gene and an adjacent immunoglobulin gene.

The results of a translocation can be:

- Activation of a gene
- Silencing of a gene
- Formation of a novel protein by fusion of coding sequences of participating chromosomes

It is the last property that has served as a template for development of a new drug (Gleevec, Novartis) that is effective **against the product of chromosomal translocation in chronic myelogenous leukemia**. The new agent also appears to be active against a group of gastrointestinal tumors known as GIST (see Chap. 24).

Many genes affected by translocations have been localized, identified, and sequenced (Mitelman and Mertens, 1997). It is now known that the genes involved are often related to the principal sites encoding immunoglobulin genes. Adjacent genes often encode for certain oncogenes. For example, the 14:18 chromosomal translocation in B-cell lymphomas affects a gene known as *bcl-2* and, in Burkitt's lymphoma, the *c-myc* gene. Both the *bcl-2* and *c-myc* genes have been shown to be **inhibitors of programmed cell death or apoptosis** and it is assumed that their mutation prevents apoptosis of genetically deficient cells and, thus,

contributes to an unregulated proliferation of abnormal cells or cancer (Sanchez-Garcia, 1997).

Tumor Clonality: Loss of Heterozygosity

Another molecular feature that is common in cancer is loss of heterozygosity. The observation is based on the premise

P.155

that the **two chromosomal homologues** in each cell **are not identical**, as one is of paternal and the other of maternal origin. It is assumed that **all cancer cells are derived from a single progenitor cell that carries the characteristics of only one parent and not both. One of the two genes may be inactivated or mutated.** This phenomenon, known as **loss of heterozygosity (LOH)**, could be first documented by studying the clonality of **X chromosome expression** in human cancer using **markers to inactive chromosomal DNA**. The most informative of these markers is X-linked human androgen receptor or **Humara** that can be effectively used in the detection of clonality of various disorders, whether malignant or benign (Willman et al, 1994). LOH can also be determined by Southern blotting searching for differences in expression of specific genes between the normal and malignant cells of the same person, using DNA amplified by polymerase chain reaction.

Angiogenesis

Another critically important factor in growth of cancer is supply of nutrients necessary to sustain the growth of cancer cells. A network of capillary vessels sustains the growth of cancer (Folkman and Klagsbrun, 1987). The molecules responsible for growth of capillaries have been identified and drugs directed against these factors are under development (Folkman, 1995). In the broad assessment of factors leading to cancer by Hahn and Weinberg (2002), **angiogenesis** is considered to be one of the five fundamental factors in the genesis of human cancer, the other four being resistance to growth inhibition, evasion of apoptosis, immortalization, and independence from mitotic stimulation.

In animal models, suppression of angiogenesis leads to regression of end-stage cancers (Bergers et al, 1999).

Immortality of Cancer Cells

In 1965, Hayflick pointed out that **normal cells have a limited life span and die after 50 generations**. These constraints are not applicable to **cancer cells, which are theoretically immortal**, as pointed out by Cairns (1975). Contrary to normal cells, given favorable conditions necessary for survival, cancer cells can live forever, and, in fact, they do so in tissue cultures. The reasons for the ability of cancer cells to proliferate without constraints are complex and not fully understood. One of the likely reasons is that cancer cells are deficient in control mechanisms protecting normal cells from faulty reproduction of DNA. In favor of this concept is the presence of the genetic defects, such as a **mutated p53**, in some cancer cells. This heritable defect in DNA control mechanisms may explain why the initial genetic changes lead to a cascade of events that result in ever increasing molecular (and chromosomal) disorders, discussed previously.

It is also possible that the chromosomes in cancer cells have a better mechanism of survival that prevents them from entering senescence, customary in normal cells. The guilty party may be the group of enzymes known as **telomerases**, enzymes governing the formation of telomeres, or the terminal endings of chromosomes (Blackburn, 1990). In normal cells, the length of the telomeres shrinks with age, presumably preventing the chromosomes from normal replication and leading to cell death after the 50 generations observed by Hayflick.

Telomerases may be overexpressed in cancer and provide additional telomeres, thus preventing the senescence of chromosomes and leading to the immortality of cancer cells (Haber, 1995). **Measuring the elevated expression of telomerase** in cells has been used in the diagnosis of cancer (see Chap. 26).

The observations on the role of telomeres and telomerase in normal and cancerous cells are somewhat paradoxical; longevity of cells (and, by implications, multicellular organisms) and cancers have a common denominator. It is a matter for pure speculation at this time whether the efforts at extending the span of normal human life will inevitably lead to cancer. The same reasoning may, perhaps, be applied to the efforts at **reversal of the malignant process by replacing damaged genes with intact genes**. Such procedures have been repeatedly and successfully performed in vitro on tissue cultures but, so far, there is no reported evidence known to us of a successful application of such a procedure to multicellular organisms in vivo. It remains to be seen what long-term consequences this sort of a genetic manipulation of complex organisms may produce.

Animal Models

Many of the relationships among genes in cancer cells have been studied in experimental models in mice and rats wherein, by special manipulations on ova, certain genes can be removed or inserted. **Knockout mice** (summary in Majzoub and Muglia, 1996) and **transgenic animals** (summary in Shuldiner, 1996) are models of gene suppression or enhancement. It is still questionable whether such animal models have direct or even indirect bearing on human cancer where rescue mechanisms surely exist that prevent single gene abnormalities from transforming normal cells into cancer cells. Nonetheless, some of the animal models shed light on mechanisms of some human cancer (see Chap. 23).

MOLECULAR BIOLOGY AND DIAGNOSTIC CYTOLOGY

The techniques of molecular biology, described in Chapter 3, have had, thus far, a relatively small impact on diagnostic cytology, and have not as yet, and perhaps never will, replace the light microscope as the principal diagnostic tool. Nonetheless, it is evident that some of these techniques already play an important role in the diagnosis, prognosis, and even treatment of human cancer and that this role may increase with the passage of time.

Some of these developments pertain to:

- Identification and quantitation of various gene products
by in-situ hybridization and immunocytochemistry, DNA, RNA, tissue arrays and proteomics
- Analysis of DNA replication and cell proliferation
- Determination of cell death (apoptosis and necrosis, see Chap. 6)
- Documentation of chromosomal abnormalities by fluorescent in situ hybridization (FISH) and other techniques (see Chap. 4)
- Application of molecular biologic techniques to the identification of cancer cells (as an example, see Williams et al, 1998, Keesee et al, 1998)
- Identification and characterization of viral agents that may play an important role in the genesis of human cancer
- Identification of infectious agents that may directly or indirectly influence the natural history of cancer

P.156

Some of the early work documented that it was possible to perform **cytogenetic studies** on aspirated samples (Kristoffersson et al, 1985). Subsequently, **gene rearrangement in aspirated cell samples** of malignant lymphoma was documented (Lubinski et al, 1988). Cleaving the patient's DNA with an appropriate endonuclease and an analysis of the DNA product by Southern blotting disclosed patterns characteristic of the disease. Such techniques have been applied to aspirated **samples of lymph nodes**. If necessary, scanty DNA samples can be subjected to polymerase chain reaction (PCR; see Chap. 3) to amplify the genes of interest. This technique has been used by Feimesser et al (1992) to document the presence of **Epstein Barr virus (EBV)** in cells aspirated from neck lymph nodes in patients with presumed **nasopharyngeal carcinoma**. Because EBV is commonly associated with this tumor, its presence was confirmatory of the diagnosis.

The fluorescent in situ hybridization technique (FISH) has been repeatedly used in aspirated samples to document **numerical abnormalities of various chromosomes** in cancer cells (early example in Veltman et al, 1997; review in Wolman, 1997; see Chaps. 23 and 26 for further comments). The presence of **chromosomal translocations** by probes to hybrid transcripts was documented by Åkerman et al (1996) in Ewing's sarcoma and in mantle cell lymphoma by Hughes et al (1998). **Reverse transcriptase polymerase chain reaction (RT-PCR)** to identify rare cancer cells in the bone marrow and circulating blood is described in Chapter 43. Nilsson et al (1998) used this technique to study translocations in synovial sarcoma.

Studies of **apoptosis** using the TUNEL reaction (see Chap. 6) have been repeatedly performed. As this chapter is being revised (2004), these techniques, including **DNA, RNA arrays, and proteomics**, are in their infancy. Still, the early experience has shown that aspirated cell samples are suitable for molecular genetic analysis and offer one major advantage—the sampling can be repeated, if needed, without surgical removal of the lesion and without harm to the patient. Li et al (1995) documented that DNA extracted from archival cell samples is suitable for polymerase chain reaction.

Application of these techniques in reference to tumors of various organs is discussed in appropriate chapters. Examples include **molecular characterization of neuroblastoma** (Fröstad et al, 1999), determination of **telomerase activity** in fluids (Mu et al, 1999), detection of **chromosomal aberrations in squamous cancer by FISH** (Veltman et al, 1997), characterization of **Ewing's sarcoma** by reverse transcriptase polymerase chain reaction on archival cytologic samples (Schlott et al, 1997), and detection of loss of heterozygote in breast aspirates (Chuaqui et al, 1996).

MORPHOLOGIC CHARACTERISTICS OF CANCER CELLS

Identification of cancer cells by a light microscopic examination is an accepted means of cancer diagnosis, **with certain limitations**. The limitations may occur under two sets of circumstances. On the one hand, self-limiting, hence, benign, **proliferative or reparative processes may occasionally mimic cancer** (see Chap. 6 and Fig. 6-10); on the other hand, **cancer cells may not differ sufficiently from normal cells of the same origin for secure microscopic identification**. Both of these sources of error are avoidable, to a certain extent, by experience and by knowledge of the clinical history. However, there are few experienced observers who will not have recorded their occasional diagnostic failure and mistakes.

Although it is very tempting to consider identification of cancer cells as a science, the truth is that it is still largely an art, which is based on visual experiences that are recorded by the human memory in a manner that defies our current understanding. **Cancer cells, like normal**

cells, are composed of a nucleus and a cytoplasm. The nucleus contains DNA and is therefore responsible for the replication of the genetic material and other events governed by DNA (see Chap. 3). As shown by electron microscopy, the cytoplasm of cancer cells contains all of the organelles necessary for energy production and other cell functions. **Thus, cancer cells are endowed with all the necessary components to sustain life and, to some extent, preserve the genetic characteristics of the tissue of origin.**

The **principal morphologic differences between benign cells and cancer cells** are shown schematically in Figure 7-8 and are summarized in Table 7-3. The differences are based on **cell size and configuration, interrelationship of cells, cell membrane, characteristics of the nucleus, and mitotic activity.** These will be discussed in sequence.

The Cytoplasm

Cell Size

The size of cancer cells usually differs from normal cells of the same origin. However, **physiologic variability in cell sizes also occurs in benign tissues.** This is particularly evident in epithelial tissues, such as squamous epithelium, wherein component cells may undergo substantial size

P.157

changes during normal maturation (see Fig. 5-4). **Cancer cells vary in size beyond the limits usually associated with physiologic variation.** Extreme size changes may be occasionally recorded; very large, sometimes multinucleated giant cells and very small cancer cells may occur. More importantly, a population of cancer cells is rarely made up of cells of equal size. **The cancer cells usually vary in size among themselves (anisocytosis)** (Fig. 7-9). These differences may be enhanced in air-dried smears stained with hematologic stains (Fig. 7-9D). However, **cell size alone is not a sufficient criterion for the diagnosis of cancer in the absence of nuclear abnormalities.**

Figure 7-8 Schematic representation of the principal differences between a hypothetical benign cell (left) and a malignant cell (right). The differences, detailed in Table 7-3, pertain to cell configuration; nuclear size, shade, and texture; nucleolar size and shape; and the cell-to-cell relationship. The last is symbolized by the desmosome present on the benign cell and absent on the malignant cell to emphasize the reduced adhesiveness among cancer cells.

TABLE 7-3 PRINCIPAL MORPHOLOGIC DIFFERENCES BETWEEN NORMAL CELLS AND CANCER CELLS

	Benign Cells	Cancer Cells
Cell size	Variable within physiologic limits	Variable beyond physiologic limits
Cell shape	Variable within physiologic limits and depends on tissue type	Abnormal shapes frequent
Nuclear size	Variable within limits of cell cycle	Significant variability (anisonucleosis)
Nucleocytoplasmic ratio	Variable within physiologic limits	Commonly altered in favor of nucleus
Nuclear shape	Generally spherical, oval, or kidney-shaped	Aberrations of shape and configuration
Chromatin texture (nondividing nucleus)	Finely granular texture, "transparent"	Coarsely granular texture, "opaque"
Hyperchromasia	Rare	Common
Multinucleation	Not characteristic	Not characteristic
Nucleoli	Small, regular in shape, limited in number	Enlarged, of irregular configuration, increased in number
Nucleolini	Small and of constant size	Enlarged and of variable sizes
Adhesiveness	Excellent (except in lymph nodes, spleen, bone marrow)	Poor
Cell junctions	According to tissue type	No conclusive evidence of abnormalities
Growth pattern in culture	Contact inhibition	No contact inhibition
Number of cell generations	± 50	Unlimited

in culture		
Effects of lectins	Not agglutinable [*]	Agglutinable
Ultrastructure of cell surface in scanning electron microscope	Ridges, ruffles and blebs (microvilli in specific sites only) [*]	Microvilli of variable configuration on the entire surface [†]
Mitotic rate	As needed for replacement [*]	Elevated
Mitoses	Bipolar [*]	Aberrant forms
Placement of mitoses in epithelium	Basal layer only [*]	Not confined to basal layer
Cell cycle duration	16-22 hr	Normal or longer

^{*} For exceptions, see text.

[†] In effusions and other fluids. Configuration still unknown in many situations.

Very little is known about the biologic events regulating cell size. It is perhaps of interest that deficiency in vitamin B₁₂, which affects the synthesis of DNA by a complex mechanism, may result in cell gigantism (see Chap. 10). It may

P.158

be inferred, therefore, that the abnormal sizes of cancer cells are the result of DNA abnormalities of a yet unknown nature.

Figure 7-9 Variable sizes and configuration of cancer cells and their nuclei. *A.* Small cell (oat cell) carcinoma of lung, bronchial brush smear. *B.* Large cells. Adenocarcinoma of lung, needle aspiration biopsy (FNA). *C.* Gastric carcinoma, metastatic to vertebra, aspirated sample. Note the variability of cell and nuclear sizes and shapes. *D.* Mesodermal mixed tumor, ascitic fluid. Note bizarre, multinucleated giant cancer cells, next to smaller cells; the features are enhanced in this air-dried Diff-Quik-stained smear.

Cell Configuration

Unusual, abnormal cell shapes may be observed in cancer cells, especially in advanced cancer (Fig. 7-9C), although cancer cell configuration may mimic, sometimes in a grotesque fashion, normal cells of the same origin. The configuration of cancer cells does not necessarily depend on the physical relationship of cancer cells to each other or to the supporting connective tissue, as had been claimed. For example, bizarre configuration may be observed in human cancer cells growing freely in effusions (see Chap. 26).

It must be added, however, that **bizarre configuration of cells may also be observed in benign processes**, particularly those associated with rapid proliferation of cells of either connective tissue or epithelial origin. Therefore, once again, **nuclear and clinical features** must be considered before rendering the diagnosis of cancer. There has been no substantial research on the factors governing cell shapes in cancer. It is likely that the configuration of cancer cells is encoded in the nuclear DNA, and translated by RNA governing the formation of structural proteins.

Cell Adhesiveness

One of the principal traits of cancer cells is their poor adhesiveness to each other.

Thus, in smears prepared from an aspirated sample of a malignant tumor, the abundant cancer cells may appear singly or in loosely structured aggregates, whereas this phenomenon cannot be fully appreciated in the corresponding histologic preparation (Fig. 7-10). Also, a smear from the corresponding benign tissue will yield cells mainly arranged in tightly fitting, orderly clusters, wherein the cell borders can be often identified (see Fig. 7-2).

There are some **differences in the adhesiveness of cells of various tumor types.**

Generally speaking, cancer **cells of epithelial origin tend to form clusters and aggregates**, even when allowed to proliferate freely (Fig. 7-10B). Poor adhesiveness is more evident in anaplastic, poorly differentiated tumors than in well differentiated tumors. On the other hand, the cells of most nonepithelial tumors, particularly **malignant lymphomas and sarcomas**, rarely, if ever, form clusters and **tend to remain single** (Fig. 7-11).

P.159

Figure 7-10 Poor adhesiveness of cancer cells. *A.* Aspirate of mammary carcinoma. The cancer cells are dispersed. *B.* Aspirate of pulmonary adenocarcinoma. The cell cluster is loosely structured. (*A:* Pap stain; *B:* May-Grünwald-Giemsa stain.)

The original observations pertaining to **decreased adhesiveness of cancer cells** were made by Coman (1944) who measured with a micromanipulator the force required to separate cells of squamous carcinoma and found it to be significantly lower when compared with normal squamous epithelium. Using a different technique, McCutcheon et al (1948) made similar observations on cells of adenocarcinomas of various origins. The causes of poor adhesiveness of cancer cells are not well understood. Coman (1961) pointed out that calcium played a major role because its removal diminished the adhesiveness. The possible **deficiencies in cell-to-cell attachments and junctions** were studied, using a variety of techniques. Normal tissues have an elaborate apparatus of cell attachments (e.g., junctional complexes, gap junctions, desmosomes, and hemidesmosomes) holding the cells together (see Chap. 2). All of these organelles have also been observed in cancer, both human and experimental. For example, Lavin and Koss (1971) showed that cultured cancer cells are capable of forming morphologically normal desmosomes. In searching for qualitative and quantitative differences in cell junctions between normal urothelium and urothelial cancer, Weinstein et al (1976) could find none and stated that in cancer “there is neither concrete nor compelling circumstantial evidence which supports the popular notion that junctional defects contribute to those properties which are the hallmarks of malignant growth, namely, invasiveness and the ability to metastasize.” This view was confirmed in a subsequent review by Weinstein and Paul (1981).

Figure 7-11 Dispersed cancer cells. *A.* Malignant lymphoma. Note mitosis and prominent nucleoli. *B.* Rhabdomyosarcoma. Note bizarre cell shapes and cells with eosinophilic cytoplasm, characteristic of this tumor.

Molecular biologic investigations, summarized earlier, strongly suggest that **alterations of adhesion molecules may be the cause of poor adhesiveness of cancer cells**. As has been stated, there is evidence that oncogenes and modified tumor suppressor genes interact with the adhesion molecules. This research is still in early stages. It has been repeatedly shown that an overexpression of adhesion signaling molecules (focal adhesion kinase) is associated with malignant transformation (Oktay et al, 2003).

From a practical point of view, **poor adhesiveness of cancer cells gives a distinct advantage to some techniques of cell sampling**. Aspiration of a cancer, whether human or

experimental, by means of a needle and syringe, will usually yield abundant cells, compared with normal tissue of similar origin. The only exceptions to this rule are normal

P.160

lymphoid organs, the spleen, and the bone marrow, which yield abundant cells also in the absence of cancer. Scraping of cancers located on the surface of organs may yield abundant free cancer cells. Cancers may spontaneously shed (exfoliate) cells into adjacent body cavities.

Cell Membranes

The interrelationship of cancer cells may also depend on cell membranes. The first objective evidence that the membrane of cancer cells may differ from that of normal cells was based on the observation of **patterns of cell growth in tissue culture**. When **normal (diploid or euploid) cells are grown on hard surfaces**, such as glass or plastic, **they show contact inhibition**, or stop growing when their borders contact each other. After the initiation of a tissue culture from a fragment of tissue or a cluster of cultured cells, the cells multiply actively and migrate away from the inoculum. This migration takes place because of an undulating movement of cell membranes. The cell migration stops once the cell membranes come in contact with each other in the state of confluent monolayer. Simultaneously, the undulations of the cell membranes cease, the mitotic rate drops precipitously, and the synthesis of DNA, RNA decrease sharply. Although contact inhibition can be manipulated by various experimental means, it generally characterizes benign cells in culture.

In contrast, **cancer cells grown on glass or plastic surfaces do not show contact inhibition**. Their growth does not stop when a confluent monolayer is formed and the cells form multilayered accumulations (piling up) (Fig. 7-12). Ambrose (1968) pointed out that malignant cells are also capable of changing the direction of their movements more frequently than normal cells. Contact inhibition may be lifted when benign cells are transformed in vitro into malignant cells by viral or chemical agents.

The precise mechanisms of the differences in the behavior of normal and cancer cells in vitro remain to be elucidated. However, it is virtually certain that these behavior patterns are governed by adhesion molecules and growth factors, as has been shown by Segall et al (1996) in reference to cultured cells of rat mammary carcinoma.

Figure 7-12 A. Growth pattern of BHK-21 benign fibroblasts growing on a glass or smooth cellulose acetate surface. B. Growth pattern of PPY polyoma-transformed (malignant) cells on glass (rough or smooth) or cellulose acetate (rough or smooth). Note overlapping of cell processes. (Ambrose EJ. The surface properties of mammalian cells in culture. *In* The Proliferation and Spread of Neoplastic Cells. Baltimore, Williams & Wilkins, 1968, pp 23-37.)

Figure 7-13 Schematic representation of effect of lectins on benign (*top*) and malignant cells (see text).

Besides behavior in culture, there are other observations that point out fundamental differences in membrane structure between benign and malignant cells. For example, there are significant differences in the effects of various substances of plant origin, known as **lectins**, such as wheat germ agglutinin (WGA) and concanavalin A (ConA), on the membranes of various benign and virus-transformed cells in culture. The general effect of lectins can be summarized as follows: (1) **dispersed benign cells are not agglutinated by lectins** and remain in suspension, and (2) **malignant cells of similar origin are agglutinated by lectins** and form clumps (Fig. 7-13). The agglutinability of benign cells may be briefly enhanced by the action of proteolytic enzymes. Also, the benign cells are agglutinable during the mitotic cycle, except the prophase. Some embryonal cells, although normal, are also agglutinable by lectins. It appears logical that the differences are based on the presence of agglutination

P.161

sites (receptors) on the cell surface. These sites are exposed on the surface of malignant cells and are hidden on the surface of benign cells (Ben-Basset et al, 1971; Inbar et al, 1972). It must

be noted that certain **lectins**, such as phytohemagglutinin and concanavalin A, **stimulate proliferation of T lymphocytes**, with resulting formation of large, immature cells (blasts) that are capable of mitotic division. This function may also reflect the presence of appropriate receptors on the surface of the cells.

Although the biochemical and biophysical differences between membranes of benign and malignant cells require further elucidation, certain fundamental structural differences have been discovered by **electron microscopy**.

Scanning and transmission electron microscopic studies of benign and malignant human cells in some tissues and in cancer cells suspended in effusions or in urine, disclosed major differences in cell surface configuration. In general, **the surfaces of benign cells, such as squamous cells, lymphocytes, macrophages, or mesothelial cells, display either ridges, blebs, or uniform microvilli. The surfaces of most (but not all) malignant cells of epithelial origin (carcinomas) are covered with microvilli of variable sizes and configuration** (Fig. 7-14A,B). One notable exception is the **oat cell carcinoma** of lung origin, wherein the surfaces of cancer cells are smooth. The microvilli on the surfaces of benign cells differ from microvilli observed on surfaces of cancer cells. **In benign epithelial cells of glandular origin, the microvilli are polarized** (i.e., confined to one aspect of the normal cell, usually that facing the lumen of a gland or organ) and are of uniform and monotonous configuration. **The microvilli of epithelial cancer cells cover the entire cell surface**, vary in size and length, sometimes forming clumps of very long microvilli. In some tumors, notably **carcinomatous mesothelioma**, tufts of long microvilli characterize the malignant cells. The microvilli on the surface of some cancer cells may be seen under the light microscope and are helpful in recognizing cancer cells (see Chaps. 26 and 27). The mechanisms of formation of

P.162

microvilli have not been investigated so far. For the same reason, the relationship of microvilli on the surfaces of cancer cells to their agglutinability with lectins is not clear. Possibly, the two phenomena are connected in a manner that remains to be elucidated.

Figure 7-14 A. Scanning electron micrograph of a breast cancer cell in effusion. The surface is covered by innumerable microvilli of variable length and configuration. *B.* Transmission electron micrograph of the surface of a cancer cell of ovarian origin, in effusion. Note the innumerable microvilli of various lengths, thicknesses, and configurations. (*A*: $\times 4,600$; *B*: $\times 25,000$.) (*A*: Domagala W, Koss LG. Configuration of surfaces of human cancer cells in effusions. *Virchows Arch* 26:27-42, 1977. *B*: Courtesy of Dr. W. Domagala.)

The Nucleus

Nuclear abnormalities are the dominant morphologic feature of cancer cells that allow their recognition in microscopic preparations. The key changes observed are:

- Nuclear enlargement, particularly in reference to the area of the cytoplasm [altered nucleocytoplasmic (N/C) ratio] in favor of the nucleus
- Irregularity of the nuclear configuration and contour
- Altered nuclear texture; hyperchromasia and coarse granulation of chromatin
- Abnormalities of sex chromatin in females
- Changes in nuclear membrane

- Nucleolar abnormalities
- Abnormalities of cell cycle and mitoses
- Special features observed in some tumors

These abnormalities will be discussed in sequence.

Size

The size and, hence, **the area of the nucleus** in smear and other cytologic preparations **depends on DNA content. The relationship is not linear.** For example, the **doubling of the amount of DNA** that occurs during the S-phase of the normal cell cycle **results in doubling of the nuclear volume, however, the nuclear diameter increases by only 40%**, a calculation based on principles of geometry. Because the nucleus in smears is flattened on the surface of the glass slide, the **nuclear diameter**, corresponding approximately to the largest cross section of the nucleus, is the dominant feature observed under the microscope.

In a normal cycling population of cells, some variability in the nuclear sizes will be observed, with larger nuclei representing cells in S, G2 phases of the cell cycle. However, under normal circumstances, the proportion of cycling normal cells is small, rarely surpassing 1% to 2%. **In most, but not all, populations of malignant cells, nuclear enlargement is a common feature, often encompassing a large proportion of cancer cells.** Because the cytoplasm of such cells is often of approximately normal size, the area of the nucleus is disproportionately enlarged, resulting in an **increase of the nucleocytoplasmic (N/C) ratio.** Because the increase in the nuclear size usually reflects an increase in the amount of DNA, in malignant tumors with approximately normal DNA content, the nuclear enlargement may not be evident but other nuclear abnormalities, discussed below, may be observed.

The amount of DNA in nuclei can be measured by techniques of image cytometry or flow cytometry (see Chaps. 46 and 47). These techniques show that in many, but not all, cancer cells there is an increase in the amount of DNA. However, **because of heterogeneity of cancer cells in many cancers, the amount of DNA varies from one cancer cell to another**, although it can be increased in many cells; some cells may have the normal (diploid) or even subnormal amounts of DNA. **Consequently, the size of cancer cell nuclei within the same cancer often varies, a phenomenon named anisonucleosis (nonequal nuclei)**, and this feature is also common in cancer (see Fig. 7-9B-D).

Because heterogeneity or the variability of size of cancer cell nuclei would make a characterization of any given cancer nearly impossible, the concept of **DNA ploidy** was established, **based on the DNA content in the dominant population of cancer cells in a given cancer and disregarding the deviant DNA values.** The concept is based on comparison of normal amount of DNA (**diploid or euploid cells**) with the DNA content in the dominant population of cancer cells. In some cancers, the DNA ploidy of cancer cells may be equal to normal (**diploid tumors**). When the DNA content deviates from normal, the tumors are **aneuploid**. Aneuploid tumors may have a DNA content below normal (**hypodiploid aneuploid tumors**), or above normal (**hyperdiploid aneuploid tumors**). Several groups may be recognized among aneuploid tumors, for example, when the dominant DNA content is one and a half times higher than normal, the tumors are classified as **triploid**; when it is twice the normal, the tumors are classified as **tetraploid**. Various other deviations from normal may occur that are neither triploid nor tetraploid (Fig. 7-15). The DNA ploidy of a tumor or a given cell population is often expressed as **DNA index, expressing the ratio between the ploidy of the tumor cell population compared with the normal index of one.** Thus, the DNA index of a tetraploid tumor, which has twice the amount of DNA, is 2.0 and that of a triploid tumor 1.5 (see Chap.

47).

If the **increase in the diameter of the nucleus** represents an increase in the amount of nuclear DNA, it also indicates an **increase in the number of chromosomes**. The number of chromosomes in cells is determined in spreads of metaphases. The total number of chromosomes is often increased in cancer cells. Not all chromosomes are affected, some chromosomes may retain their normal number and configuration, whereas others may show numerical and morphologic abnormalities (see Chap. 4). There is a fairly good concordance between the DNA content and the number of chromosomes per cell. However, once again to reflect the heterogeneity of cancer cells, the term **stem line**, rather than ploidy, is used in the classification of human tumors based on cytogenetic findings. Again, the stem line designates the dominant cell population with an approximately constant number of chromosomes. The stem line may be **diploid** or **euploid** (corresponding to 46 chromosomes), or **aneuploid**, **corresponding to abnormalities in the number of chromosomes**. Thus, one can recognize triploid tumors, corresponding to 69 chromosomes, tetraploid tumors (92 chromosomes), or tumors with variable deviations from normal, in keeping with the terminology of DNA ploidy. It is evident from this information that **the size of the cancer cell nucleus in smears depends, to a large extent, on the number of chromosomes or tumor stem line**. This was documented many years ago in a study conducted by Miles and Koss (1966). The aggregate length of all chromosomes

P.163

was measured in cells of several cultured cell lines and compared with the sizes of the nuclei (Fig. 7-16). A diploid embryonal rhabdomyosarcoma with 46 chromosomes (Fig. 7-16A,B) had small, bland nuclei. Cultured cells from several epidermoid carcinomas, with stem lines between 59 and 70 chromosomes, show larger nuclei (Fig. 7-16D-F). A malignant melanoma, with a stem line of 123 chromosomes (Fig. 7-16G), shows the largest nuclei. In Figure 7-16 panels C through G, abnormalities of nuclear chromatin are also observed (see below).

Figure 7-15 Dominant DNA ploidy values, as determined by Feuglen spectrophotometry, of 111 carcinomas of the corpus uteri (*top*), 392 squamous cell carcinomas of the cervix uteri (*middle*), and 85 carcinomas of the large bowel (*bottom*). D and T signify diploid and tetraploid DNA levels, respectively. It may be noted that for all three cancer sites the dominant modal DNA content is predominantly aneuploid although some cancers are diploid, and a few are tetraploid. (Atkin NB. Cytogenetic studies on human tumors and premalignant lesions: The emergence of aneuploid cell lines and their relationship to the process of malignant transformation in man. *In* Genetic Concepts and Neoplasia. Baltimore, Williams & Wilkins, 1970, pp 30-56.)

Another approach to document numerical or functional abnormalities of chromosomes in individual cancer cells is the technique of **in situ hybridization**, based on biotinylated (and hence visible in light microscopy) or fluorescent specific probes to entire chromosomes, or to chromosomal segments, such as centromeres, or to individual genes. The principles of the technique were discussed in Chapter 4. The technique examines **interphase nuclei** and, thus, may be applied to any population of cells. The basic assumption of the technique is that, in normal cells, there are two homologues of each chromosome. The presence of more than two

signals indicates a chromosomal abnormality that, for all intents and purposes, is diagnostic of cancer, unless the patient has a congenital abnormality in chromosomal numbers, such as trisomy of chromosome 21. The technique has been used as a diagnostic tool to document the presence of chromosomal abnormalities in cells from different body sites, such as effusions, bladder washings, and material from aspiration biopsies (Cajulis et al, 1993, 1997). With the development of new probes, the technique can be applied to the search for aberrant genes, translocations, etc. (summaries in Glassman, 1998; Luke and Shepelsky, 1998). Examples of this technique are shown in Chapters 4 and 23.

As previously discussed and in Chapter 4, **besides numerical abnormalities, the chromosomes in cancer cells may show a variety of other changes, such as translocations and marker chromosomes.**

It is evident from the earlier discussion that **nuclear size alone may be helpful in the diagnosis of malignant tumors with elevated DNA or chromosomal content but will fail in the recognition of tumors with normal or nearnormal DNA content (diploid or near-diploid tumors).** If the changes in nuclear size are subtle, the microscopist should always **compare the nuclear size of the unknown cell with a microscopic object of known size**, such as an erythrocyte (7 μm in diameter) or the nucleus of a recognizable benign cell. Subtle differences in size are of limited diagnostic help and the search for other nuclear features is necessary.

Irregularities of the Nuclear Configuration and Contour

The configuration of the nuclei in normal cells usually follows the shape of the cytoplasm. Most nuclei, in benign spherical or polygonal epithelial cells, are spherical. In cells of columnar shape, the nuclei are usually oval. Nuclei of elongated epithelial cells, fibroblasts, or smooth muscle cells are often elongated and sometimes spindle-shaped. Nuclear configuration of highly specialized cells probably reflects highly specialized functions. Thus, the nuclei of macrophages may be kidney-shaped and those of polymorphonuclear leukocytes and megakaryocytes show lobulations. It is not known, at this time, why this is so or what factors influence the shape of the nucleus. Hypothetically, it would be logical to assume that nuclear configuration and shape are optimal for most efficient nucleocytoplasmic exchanges and, hence, cell function in any given cell type. **Still, the nuclei of all benign cells have a smooth nuclear contour.**

The configuration of the nuclei of cancer cells also generally follows the configuration of the cells. Thus, most spherical or polygonal cancer cells have approximately spherical or oval nuclei. Elongated or “spindly” cancer cells have elongated nuclei. However, these nuclei often show **abnormalities of the nuclear contour**, best observed in spherical or oval nuclei. These abnormalities may be subtle, in the form of **small protrusions or notches**, in the nuclear membrane that may be difficult to observe and may require a careful inspection of the target cells (Fig. 7-17). Less often, the nuclei may show **fingerlike protrusions** that were attributed in the very few pertinent studies to the presence of long marker chromosomes (Atkin and Baker, 1964; Atkin, 1969; Kovacs, 1982). It must be noted that **dense nuclear protrusions** (“nipples”), possibly an artifact, also occur in certain benign cells, such as endocervical cells (see Chap. 8).

Figure 7-16 Impression smears of tumors with varying chromosomal numbers. *A,B*. Same tumor, an embryonal rhabdomyosarcoma with 46 chromosomes and a normal karyotype. *C*. A soft part sarcoma, 47 chromosomes. *D-F*. Epidermoid carcinomas with stemlines of 59, 66-67, and 70 chromosomes, respectively. *G*. Represents a malignant melanoma with stemline of 123 chromosomes. Note that the diploid tumor (*A,B*) exhibit small, relatively bland nuclei. All of the aneuploid tumors, even the one (*C*) with one extra chromosome, exhibit large hyperchromatic pleomorphic nuclei. (All oil immersion.) (Miles CP, Koss LG. Diagnostic traits of interphase human cancer cells with known chromosome patterns. *Acta Cytol* 10:21-25, 1996.)

Figure 7-17 Abnormalities of the nucleus in cancer cells. *A.* Aspirate of pancreatic carcinoma. *B.* Aspirate of neuroblastoma. *C,D.* Urothelial carcinoma. Coarse granulation of chromatin and subtle abnormalities of nuclear contour (notches and protrusions) may be observed in all photographs. (Pap stain; *A*: high magnification; *B-D*: oil immersion.)

In elongated cancer cells and most nonepithelial cells with elongated nuclei, the abnormalities of the nuclear contour are more difficult to recognize, although sometimes spinelike protrusions may be observed at one pole. In bizarre cancer cells that are sometimes multinucleated, bizarre configuration of nuclei may be observed (see Fig. 7-9D).

The abnormalities of the nuclear configuration and contour, particularly when associated with nuclear enlargement and an increase in the nucleocytoplasmic ratio, raise a high level of suspicion for the diagnosis of cancer and are usually associated with other stigmata of cancer cells.

Several observers attempted to correlate the configuration of nuclei of human tumors in histologic sections with behavior and prognosis (Miller et al, 1988; Borland et al, 1993). The observations reported may reflect a fixation artifact and, more remotely, the chromosomal makeup of the tumors studied.

Nuclear Texture: Hyperchromasia and Coarse Granulation of Chromatin

Dark staining of interphase nuclei of cancer cells with appropriated dyes, such as hematoxylin or acetic orcein, is known as **hyperchromasia**. **Hyperchromasia is usually associated with changes in configuration of nuclear chromatin, which shows coarse granulation** and may be associated with a **thickening of the nuclear membrane** (Fig. 7-17). By contrast, normal fixed and stained nuclei have a transparent nucleoplasm, with a fine network of filaments of **constitutive chromatin**, which forms small dense granules known as **chromocenters**. In females, the **sex chromatin body** (Barr body), representing **facultative chromatin**, may be observed as a dense, semicircular structure attached to the nuclear membrane (see Chaps. 2 and 4).

Tolles et al (1961) documented objectively the presence of hyperchromasia in cancer cells from the uterine cervix by measuring the extinction coefficients. Several studies based on computerized image analysis also documented that the changes in nuclear texture are an

objective parameter separating cancer cells from normal cells of the same origin (see Chap. 46). The reasons for coarse granulation of chromatin are essentially unknown and have not received any attention from molecular biologists. A few speculative

P.166

thoughts can be offered. There is evidence that **the condensed DNA of some cancer cells has a lower melting point than DNA of normal cells**. In other words, the two chains of DNA in cancer cells are easier to separate than the two chains of normal DNA (Darzynkiewicz et al, 1987). The issue has been studied further by Darzynkiewicz and his associates (1987) who suggested that the condensation of chromatin is associated with structural nuclear proteins. Atkin (1969) spoke of “**telophase pattern**” of chromatin in cancer cells, suggesting similarities in the distribution of coarsely granular DNA in cancer cells with chromatin distribution in normal telophase. Another analogy may be offered with condensation of chromosomes in prophase of mitosis. However, neither analogy corresponds to the reality because only a small fraction of cancer cells displaying hyperchromasia are undergoing mitosis. The only reasonable conclusion that is permissible, at this time, is that the **DNA in cancer cells has undergone significant structural changes of unknown nature** that accounts for hyperchromasia and coarse granulation of chromatin. Stein et al (2000) proposed that the abnormalities of nuclear structure in cancer reflect altered gene expression. However, the mechanisms and function of these changes are enigmatic. Gisselsson et al (2000, 2001) attributed the nuclear abnormalities to **chromosomal breakage and fusion** of fragments (**breakage fusion bridges**). The concept is interesting and warrants further exploration but fails to explain the coarse granularity of chromatin so common in the nuclei of cancer cells.

It must also be stressed that hyperchromasia and coarse granularity of chromatin may be absent in cancer cells. Numerous examples of invasive cancer of various organs have been observed wherein **nuclei of cancer cells are enlarged but completely bland and transparent**. In some of these cells, **enlarged nucleoli** can be observed. These abnormalities are most often observed in clusters of cells with generally abnormal configuration and are usually accompanied elsewhere by more conventional cancer cell abnormalities. Thus, the finding of **cell clusters with large bland nuclei is, a priori, abnormal** and should lead to further search for evidence of cancer.

It must also be stressed that **nuclear enlargement and hyperchromasia may occur in normal organs**, such as the embryonal adrenal cortex and endocrine organs, for example, the acini of the thyroid gland (see Chap. 30). Thus, the provenance of the material is of capital significance in assessing the value of the microscopic observations.

Abnormalities of Sex Chromatin in Females

Sex chromatin body (Barr body) represents the inactive X chromosome in female cells (see Chap. 4). The formula pertaining to the number of Barr bodies visible on the nuclear membrane, is $X - 1$, X representing the total number of X chromosomes in a cell. Thus, a patient with 3 X chromosomes will have two Barr bodies. Because the naturally occurring excess of X chromosomes is exceedingly rare, **the presence of two or more sex chromatin bodies in a nucleus is clear evidence of genetic abnormality that may be observed in cancer cells** (Fig. 7-18). The finding is particularly helpful in situations where other nuclear stigmata of cancer are not clearly evident and may have prognostic significance in mammary carcinoma (see Chap. 29). We found it to be of particular value in identifying cells of mammary carcinoma in effusions and in recognizing cancerous changes in cervicovaginal smears (see Chaps. 11 and 26).

Figure 7-18 Breast cancer cell with two sex chromatin bodies (arrow). For further examples, see Chapters 26 and 29. (Orcein stain; oil immersion.)

Abnormalities of Nuclear Membrane

It has been previously mentioned that in many cancer cells displaying coarse granularity of chromatin, **the nuclear membrane appears thickened**. On close scrutiny, the thickness of the nuclear membrane is variable and irregular. It is not known whether this optical feature of a cancer cell nucleus, which is sometimes of diagnostic value, represents an **actual physical change in the structure of the nuclear membrane or merely a deposition of chromatin granules (or modified chromosomes) along the nuclear envelope**. Electron micrographs of cancer cells strongly suggest that deposition of chromatin (and hence chromosomes) on the nuclear membrane is the more likely explanation of this phenomenon.

Another feature of cancer cells is the **increase in the number of nuclear pores** (Czerniak et al, 1984). Although this observation has no practical value because the freeze-fracture techniques required are too cumbersome for a clinical laboratory, the observations have some bearing on understanding the metabolic processes in cancer. The Czerniak study, which was based on cells of urothelial tumors, disclosed a **relationship between DNA ploidy and the density of the nuclear pores**; the pore density was higher in tumors with increased amounts of DNA (and hence the number of chromosomes). On the other hand, the density of the pores in reference to the nuclear volume remained approximately constant. Because the nuclear pores represent a link between the nucleus and the cytoplasm, the observation suggests that the increased exchanges between the nucleus and the cytoplasm take place in cancer cells. As has been discussed in Chapter 2, the observation supports the

P.167

hypothesis that the formation of nuclear pores is closely related to organization of chromosomes in the nucleus. Further studies of this observation are clearly indicated (Koss, 1998).

Multinucleation in Cancer Cells

Cancer cells with two or more nuclei are fairly common. In some cells, such as the **Reed-Sternberg cells** in Hodgkin's disease, the finding of the specific arrangement and configuration

of the nuclei is of great diagnostic significance (see Chap. 31). However, in other tumors, the phenomenon is fairly common and of little diagnostic significance. It must be recognized that **multinucleation is a common phenomenon that may occur in benign and in malignant cells and, therefore, is of no diagnostic value, unless the configuration or arrangement of the nuclei is specific for a disease process.**

Other Nuclear Changes in Cancer Cells

In some malignant tumors, nonspecific nuclear abnormalities may occur that may be of diagnostic help. For example, in some thyroid carcinomas, malignant melanomas, and occasionally other cancers, **cytoplasmic intranuclear inclusions** appear as clear areas within the nucleus (**nuclear cytoplasmic invaginations, Orphan Annie nuclei**) (Fig. 7-19A). In electron microscopy, the clear zones contain areas of cytoplasm with cytoplasmic organelles, such as mitochondria (see Fig. 6-6). Nothing is known about the mechanism causing this nuclear abnormality, which, incidentally, can also occur in some benign cells, such as hepatocytes and ciliated bronchial cells. Another nuclear abnormality is **nuclear “creases,” “grooves,”** or folds (Fig. 7-19B). The changes may appear as **dark, thin lines** within the nucleus or as linear densities with numerous short lateral processes, sometimes referred to as **“caterpillar nuclei”** or Anitschkow cells. These nuclear features have been observed in a **variety of normal cells**, such as squamous cells of the oral cavity, cornea, or uterine cervix, and in mesothelial cells (see appropriate chapters for further comments). Deligeorgi-Politi (1987) observed numerous nuclear grooves in aspirated cells of thyroid carcinomas, an observation that has been confirmed many times. Subsequently, such nuclear changes have been observed in many different benign and malignant tumors, such as granulosa cell tumors of the ovary (Ehya and Lang, 1986) and ependymomas (Craver and McGarry, 1994), to name a few. In some tumors and conditions discussed throughout this book, the grooves are particularly numerous and their presence may be of diagnostic help (review in Ng and Collins, 1997). However, these nuclear changes should **never be considered as diagnostic of any entity** as concluded by Tahlan and Dey (2001).

Figure 7-19 Intranuclear cytoplasmic inclusions (nuclear “holes”) and nuclear grooves or creases. *A.* Intranuclear cytoplasmic inclusions. Note the sharp borders of the clear intranuclear space. Metastatic malignant melanoma to liver. *B.* Smear of a Hürthle cell tumor of thyroid. Nuclear folds or creases are seen as a diagonal line (*arrow*). (*A:* Oil immersion; *B:* high magnification.)

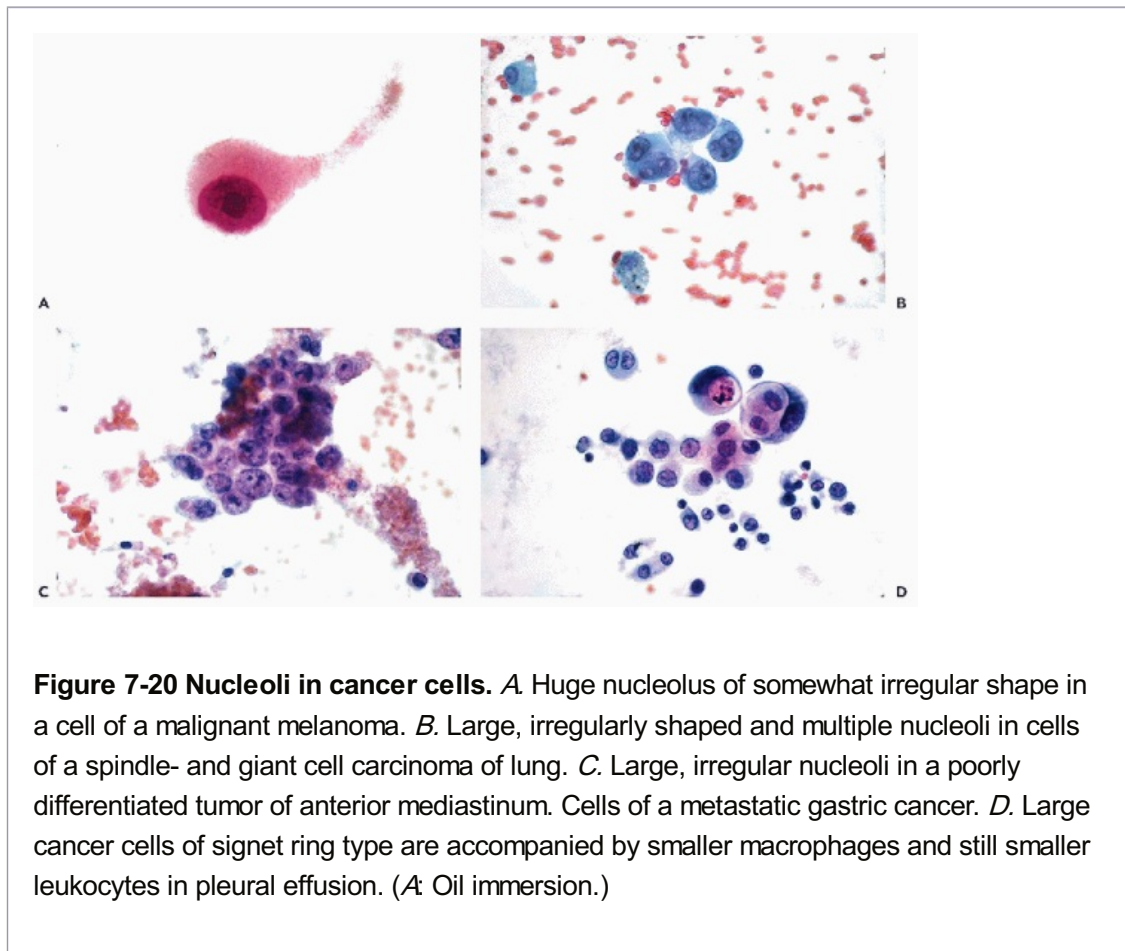

Nucleolar Abnormalities

Nucleolar abnormalities are an important feature of cancer cells. The nucleoli are characterized by their eosinophilic center, surrounded by a border of nucleolus-associated chromatin (see Chap. 2). **The number and size of nucleoli in cancer cells is often increased and their configuration may be abnormal. Very large nucleoli (5 to 7 μm in diameter, macronucleoli) are, for all practical purposes, diagnostic of cancer (Fig. 7-20). Oddly, comma-shaped nucleoli, that the late John Frost called “cookie-cutter nucleoli,” are fairly common in cancer cells. The reasons for this abnormality are unknown. The abnormality in the shape of the nucleoli is a valuable diagnostic marker because it is rarely observed in repair reactions wherein the number and size of nucleoli can be substantially increased.**

It may be recalled that, in normal cells, nucleolus-organizing foci are found on terminal portions of chromosomes 13, 14, 15, 21, and 22, resulting in formation of up to 10 small nucleoli. Shortly after mitosis, the nucleoli merge to form usually one or two somewhat larger nucleoli. Because the nucleoli are the principal **centers of synthesis of nucleic acids**, their presence in the nuclei of normal cells reflects their protein requirement. Therefore, nearly all growing or metabolically active cells carry visible, albeit small nucleoli. **However, during regeneration of normal tissues (so-called repair reaction), when the need for cell**

P.168

growth and, hence, protein synthesis is great, large, and sometimes multiple, nucleoli may be present.

Although abnormalities in the number and size of nucleoli in cancer cells were recorded by several observers in the 1930s (Haumeder, 1933; Schairer, 1935), the first objective data on the relationship of nucleoli to cancer were provided by Caspersson and Santesson (1942). Using ultraviolet spectrophotometry, these authors observed that there was a reciprocal relationship

between the size of the nucleoli and the protein content of the cytoplasm of cancer cells. In cells located near blood vessels, the cytoplasm was rich in protein and contained small nucleoli (**Type A cells**). In cells distant from the blood vessels, the nucleoli were large and the amount of protein in the cytoplasm was small (**Type B cells**). It is logical that, in cancer cells with rapid growth and, therefore, high requirements for proteins, the nucleoli should be large and multiple. This was documented objectively by Long and Taylor (1956) in cells of **ovarian and endometrial cancers. The proportion of cancer cells with multiple nucleoli (up to five per cell), particularly in poorly differentiated tumors, was much larger than in benign ovarian tumors** and the differences were statistically significant.

The increase in the number of nucleoli in cancer cells may be reflected in an **increase in the number of the nucleolar organizer sites (NOR)**. These sites, which are constituted by open loops of DNA, can be revealed by **staining cells with silver salts (AgNOR)**. After reduction of the silver salts to metallic silver the nucleolar organizer sites appear as black dots within the nucleus (Goodpasture and Bloom, 1975; review in Ruschaff et al, 1989). The assumption of such studies is that the **increase in the number of NORs per cell is indicative of a greater proliferation potential of the target tissue**. In general, cancer cells have a greater number of NORs than normal cells of the same origin. The method has been extensively applied to aspirated cell samples with questionable results (review in Cardillo, 1992).

The Nucleolini

Ultrastructural studies of nucleoli reveal the presence of two components—granular and fibrillar. The fibrillar component apparently corresponds to **small, round structures (nucleolini)** that may be observed within the nucleolus with the light microscope after staining with toluidine blue molybdate (Love et al, 1973). By the use of this method, it has been shown that the **nucleolini have a much greater variability in size and distribution (anisonucleolinos)**

P.169

in cancer cells than in benign cells. These observations originally made on cells in tissue culture, have been extended to diagnostic human material by Love and Takeda et al (1974) (Fig. 7-21).

Figure 7-21 Nucleolini in a benign mesothelial cell (*A*) and a cell of metastatic adenocarcinoma (*B*) from a pleural fluid stained with toluidine blue molybdate. The small, even size of the nucleolini in the benign cell may be compared with the size variability in the malignant cell (anisonucleolinos). (Oil immersion.) (Courtesy of Dr. M. Takeda,

Cell Cycle and Mitoses

Cell Cycle

The principal characteristic of cancer cells is their uninhibited proliferation. **Clinically, the rate of proliferation of a cancer can be measured as doubling time of tumor volume**, using either clinical judgment or radiologic data. The doubling time may vary significantly from one cancer to another. There are two possible explanations for this phenomenon: (1) either the duration of the cell cycle is shortened, resulting in more frequent replication of the same cells, or (2) the number of cells undergoing mitosis is increased.

It is **commonly and erroneously assumed that the duration of the cell cycle** (time required for replication of the DNA, for the mitosis) **is much shorter in cancer cells than in normal cells. This is not true.** Both in the experimental systems and in humans, the **duration of the cell cycle in cancer cells is variable, very rarely shorter, and usually very much longer than normal.** Early studies by Clarkson et al (1965), and by others, documented that, in human cancers, cell cycle may be extended from the normal 18 hours to several days. Therefore, this mechanism cannot account for rapid growth of some malignant tumors. **Rather, it is the proportion of cells undergoing mitosis (mitotic rate) that is increased in cancer.**

Mitotic Rate

It has been observed, in experimental tumors, that the number of cells in mitosis increases substantially within hours or days after administration of a carcinogenic agent. Bertalanffy (1969) compared mitotic rates in normal, regenerating, and malignant cell populations in epidermal cell, mammary gland, and liver parenchyma in rats (Table 7-4). In general, **the mitotic rate of malignant tumors exceeded significantly the rate for normal tissues of origin.** However, the mitotic rate of regenerating or stimulated normal tissues (for instance, the breast in pregnancy or the regenerating liver after partial hepatectomy) could exceed the mitotic rate of cancer. There are, however, some significant differences. **The high mitotic rate of regenerating or stimulated benign tissues is a temporary phenomenon, followed by a return to normal values** once the reparative events have taken place or the stimulus has ceased. **In cancer, the high mitotic rate is usually a sustained phenomenon. In proliferating normal tissues, the mitotic rate usually matches the rate of cell loss. The mitotic rate in cancer is not offset by an equivalent cell loss.** The phenomenon of apoptosis, regulating normal cell growth, is reduced in cancer (see Chap. 6).

Although **mitotic counts** represent a method of assessing the proliferative potential of tissues and cells, the method is generally not reproducible and tedious. Another way to assess the proliferative potential of tumors is a determination of the proportion of proliferating cells by **[3H]thymidine incorporation, the estimation of cells in S-phase of the cycle** by flow cytometry or image analysis, or by determining the proportion of cells in a tumor expressing **proliferation cell nuclear antigen (PCNA), or reacting with the antibody Ki67.** Measuring the **incorporation of 5-bromodeoxyuridine (BRDU)** and replacing thymine in the DNA chain, is yet another way of determining DNA proliferation in cell populations (Gratzner, 1982; Rabinovitch et al, 1988). These issues are discussed in Chapters 46 and 47. In general, most malignant tumors show an increase in the proportion of proliferating cells when compared with normal tissue of the same origin, although there may be serious problems with the techniques and the interpretation of results.

TABLE 7-4 COMPARISON BETWEEN 6-HOUR MITOTIC RATES OF NORMAL AND NEOPLASTIC CELL POPULATIONS

Cell Population	Mean 6-hr Percentage of Mitosis
<i>Epidermis (mouse)</i>	
<i>Normal</i>	
Interfollicular and follicular wall epidermis	1.2-2.2
Hair matrix	29.8
<i>Tumors</i>	
Keratoacanthoma	3.4-6.5
Carcinoma	5.6
<i>Mammary Gland (rat)</i>	
<i>Normal</i>	
Virgin, lactation, involution	0.4-0.7
Pregnancy	0.4-4.4
<i>Tumors</i>	
Adenocarcinoma	0.4-8.4 (Ave. 2.2)
<i>Liver (rat)</i>	
Normal	0.02
Regeneration	0.7-16.2
Hepatoma	1.6-10.8

These data illustrate that the epidermal and mammary gland cancers proliferate faster than the normal cell populations of the same origin. Yet during some physiologic activities, the mitotic rate of normal cell populations may increase to exceed those of malignant tumors of the same origin (for instance: hair matrix or mammary gland during

pregnancy). Similarly, mitotic activities of regenerating liver parenchyma may exceed that of a malignant hepatoma.

(Bertalanffy FD. In Fry R, Griem M, and Kirsten W (eds.). Normal and Malignant Cell Growth. New York, Springer, 1969.)

Abnormal Mitoses

Mitotic abnormalities have been recognized for many years as a common occurrence in malignant tumors. Boveri (1914) attempted to explain malignant growth as a consequence of mitotic abnormalities. The causes of mitotic abnormalities are not well understood.

Causes and Types of Mitotic Abnormalities

As originally proposed by Stubblefield (1968), it is thought today that the cause of mitotic abnormalities are disturbances in the formation of mitotic spindle (Zhou et al, 1998; Duesberg, 1999; Wilde and Zheng, 1999; Megee and Koshland, 1999; Kahana and Cleveland, 2001; Piel et al, 2001). The key to the abnormalities appears to be centrosome formation, which is governed by a complex of genes, among which p53 appears to play an important role (Fukasawa et al, 1996).

The mitotic abnormalities may be quantitative, qualitative, or both. The term **abnormal mitoses** refers to mitotic figures with abnormal number or distribution of chromosomes or an excessive number of mitotic spindles, hence, more than two mitotic poles (**multipolar mitoses**). The history of identification of mitotic and chromosomal abnormalities in cancer was summarized by Koller (1972), who also contributed a great deal of original work in this field. The following summary, modified from Koller's work (1972), describes the principal abnormalities, illustrated in Fig. 7-22.

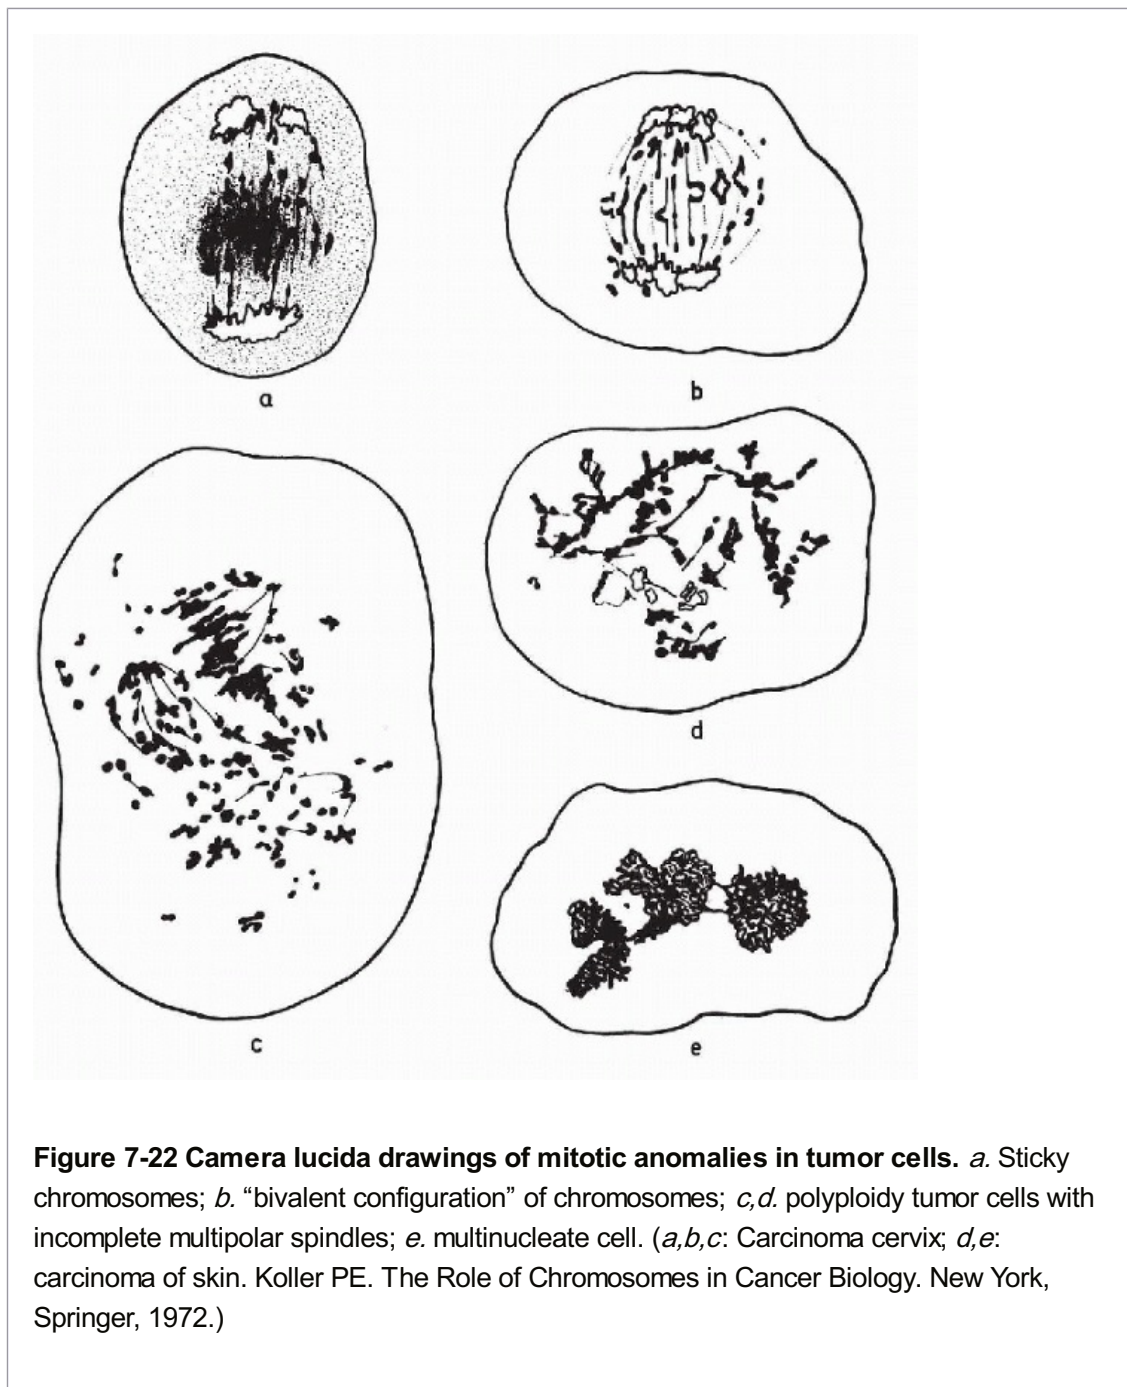

Defects in movement of chromosomes: Stickiness of chromosomes results in clumping or formation of metaphase bridges, preventing proper separation during metaphase.

Nondisjunction: Failure of separation of chromosomes during anaphase results in uneven division of the chromosomal complement between the daughter cells.

Chromosomal lag: Chromosomal lag reflects the failure of some chromosomes to join in the movement of chromosomes during ana-, meta-, or telophase. In such cells, some chromosomes remain at both poles of the spindle, whereas most chromosomes migrate to form the metaphase plate.

Abnormalities of the mitotic spindle: Such abnormalities result in multipolar mitoses with three, four or, rarely, more sets of centromeres (Fig. 7-23A). Perhaps the best known example of these abnormalities is the so-called **tripolar mitosis** (Dustin and Parmentier, 1953), often seen in carcinoma in situ of the uterine cervix, but not unique to this disease (Fig. 7-23B).

Abnormal number of chromosomes: The results of abnormalities of the mitotic spindle are either cells with **abnormal numbers of chromosomes** or gigantic tumor cells with numerous nuclei. The numerical abnormalities are more frequent than multipolar mitoses and are observed in **metaphases of cancer cells**. Excessive numbers of chromosomes are readily evident in metaphase rosettes and rarely require counting (Fig. 7-23C,D). Although tumor cells with an abnormal number of chromosomes may be viable, the fate of the monstrous caricatures of cells resulting from abnormal mitoses is uncertain. They probably represent evil-looking, but innocuous "gargoyles" of cancer, with no other future but ultimate death.

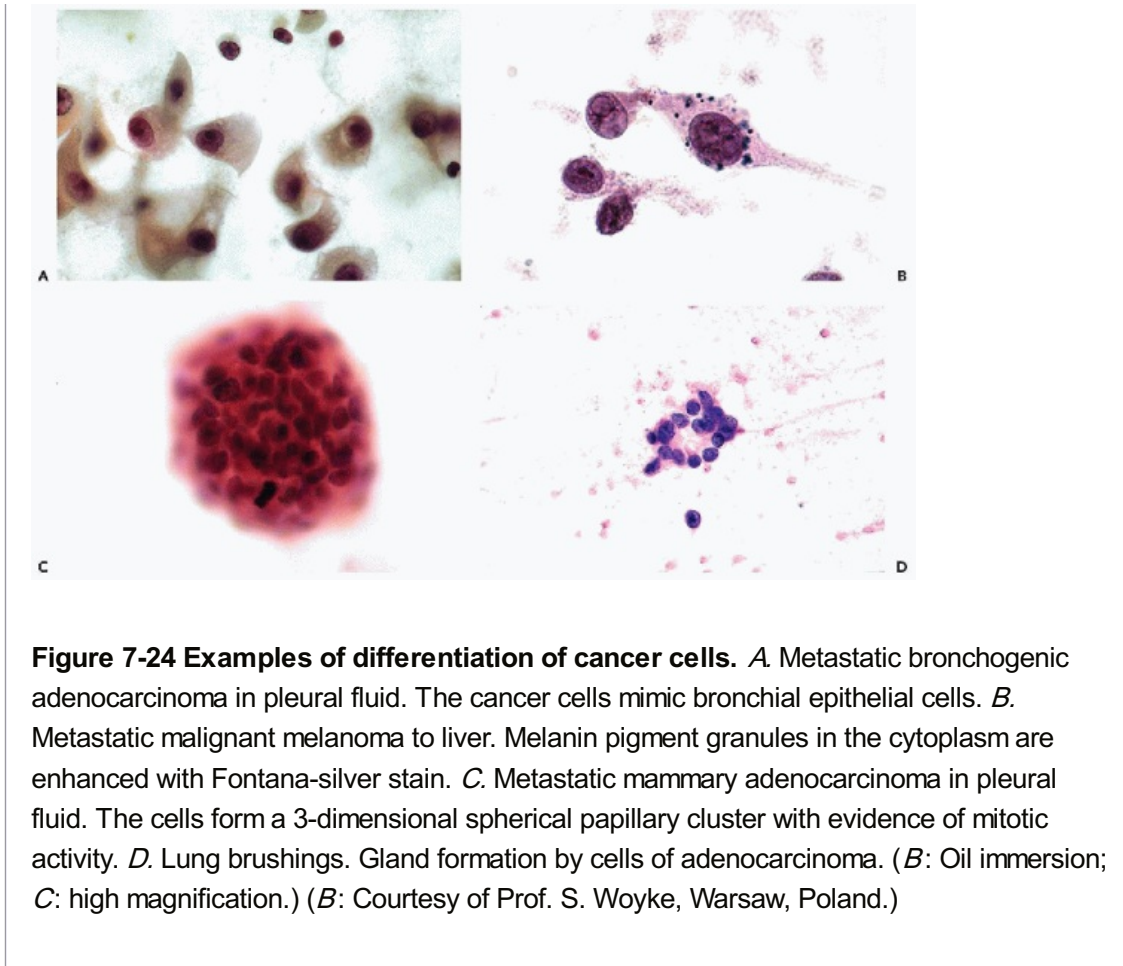

Figure 7-23 Mitotic abnormalities in cancer cells. *A.* Quadripolar mitosis, metastatic carcinoma to pericardial fluid. *B.* Tripolar mitosis, embryonal carcinoma, testis. *C.* Lung cancer, bronchial brush. (*A,B*: High magnification; *D*: oil immersion.) (*A* and *B* Courtesy of Dr. Carlos Rodriguez, Tucumán, Argentina.)

P.172

Mitoses in abnormal locations: Another abnormality observed in cancer is the presence of mitotic figures, whether morphologically normal or abnormal, in abnormal location. This is particularly applicable to situations **where the cancerous process is anatomically well-defined and polarized** as, for example, in squamous **carcinoma in situ**. In this disease (see Chap. 11), the presence of mitotic figures may be observed at all epithelial levels, whereas in normal epithelium, the mitotic activity is confined to the basal layer. Similarly, mitotic figures occurring within cancerous, mucus-secreting, glandular acini may be observed, whereas such activity is usually not obvious in mature glandular cells. It must be emphasized, however, that mitotic activity in abnormal location **may occur in benign tissues** as a result of reaction to injury or repair. In such instances, the mitoses usually occur in waves and then subside once the reparatory process has been completed.

Although, exceptionally, an abnormal mitosis may be encountered in the absence of cancer (see Fig. 6-9), it has been my experience that, **as a general rule, abnormal mitotic figures in cytologic material are associated with cancer and, therefore, constitute an important diagnostic clue.**

RECOGNIZING THE TYPE AND ORIGIN OF CANCER CELLS

Although the recognition of the malignant nature of cancer cells is based primarily on the nuclear features, the cytoplasmic features often reflect their origin and derivation of these cells. The issue is important because the recognition of cell derivation may be of significant diagnostic and clinical value, particularly in the classification of metastatic tumors of unknown origin. As a general principle, **cancer cells attempt, at all times, to mimic the tissue of origin with variable success and these attempts are expressed in the cytoplasm.** Thus, cancer cells of bronchial origin may mimic bronchial cells (Fig. 7-24A). Cancer cells of **squamous epithelial origin** often contain an abundance of **keratin filaments of high molecular weight**; this is reflected in **rigid polygonal shape** and intense **eosinophilic staining**

P.173

of the cytoplasm, easily recognizable under the microscope. The formation of squamous “pearls,” i.e., spherical structures composed of squamous cells surrounding a core of keratin, is commonly observed in squamous cancers (see Chaps. 11 and 20). The cytoplasm of cancer cells originating in the **glandular epithelium** may show evidence of **production and secretion of mucin** or related substances in the form of cytoplasmic vacuoles; such cells may also retain the **columnar configuration** of cells of the epithelium of origin. Cancer cells derived from **striated muscle** may display **cytoplasmic striations** and cells derived from pigment-producing malignant tumors, such as melanomas, may produce cytoplasmic deposits of **melanin pigment** (Fig. 7-24B).

It is not uncommon for differentiated cancer cells to form three-dimensional structures mimicking the structure of the tissue of origin. Thus, formation of **gland-like or tubule-**

like structures is fairly common in adenocarcinomas, as is the formation of spherical or oval three-dimensional clusters of cancer cells, mimicking the formation of papillary structures of the tumor observed in tissue sections (Fig. 7-24C,D). Leighton (1967) devised an experimental system of tissue culture wherein cancer cells may be observed to form three-dimensional structures mimicking the tissue of origin or its function, such as formation of melanin (Fig. 7-25).

Figure 7-25 Growth pattern of human tumors on cellulose sponge matrix coated with fibrin. *A*. Papillary carcinoma of thyroid. Note formation of colloid-filled acini. *B*. Primary culture of fibroblasts with a secondary culture of malignant melanoma. Note pigment formation. (Courtesy of Dr. Joseph Leighton, Philadelphia, Pennsylvania.)

In many cancer cells, however, the efforts at differentiation are stymied, resulting in cells that have very few or no distinguishing features under the light microscope. Such cells are classified as “**poorly differentiated**” or “**anaplastic**” (from Greek, *ana* = again and *plasis* = a moulding), suggesting a reversal to a more primitive, embryonic type of cell. Still, even **such cells may display features of sophisticated differentiation by electron microscopy or**

by **immunostaining**. For example, cells derived from poorly differentiated tumors of the **nervous system**, such as neuroblastomas,

P.174

may show ultrastructural evidence of formation of characteristic cell junctions (synapses), and of neurofibrils (see Chap. 40). Cells derived from tumors with **endocrine function** may show evidence of hormone formation in the form of the characteristic cytoplasmic vesicles in electron microscopy. The endocrine function may also be revealed by immunocytochemistry with antibodies to the endocrine granules in general or to the specific cell product. Many such examples could be given. Immunocytochemistry, discussed in detail in Chapter 45, may be applied in an attempt to determine the origin on undifferentiated cancer cells. An overview of the fundamental reagents is given in Table 7-5. The issue of cell differentiation in cancer is further complicated by the fact that **the expressions of differentiation may vary, not only from cell to cell within the same tumor, but may depend on the clinical presentation of the same tumor**. As an example, a poorly differentiated primary carcinoma of squamous or glandular lineage may become fully differentiated in a metastatic focus and vice versa; a well differentiated primary tumor may form poorly differentiated metastases. Further, a tumor that may appear to be of a single lineage in its primary presentation may form metastases showing two or sometimes more families of cancer cells. **In general, during the natural history of a cancer, recurrent or metastatic tumors tend to be less well differentiated than the primary but there are many exceptions to this rule.**

TABLE 7-5 CANCER CELL MARKERS*

Marker	Tumor Expression	Remarks
<i>Oncofetal Antigens</i>		
Carcinoembryonic antigen	Tumors of the gastrointestinal and respiratory tracts	Occasionally useful in diagnosis Used in monitoring of patients
Alphafetoprotein	Germ cell tumors of ovary and testis; primary hepatomas	Useful in diagnosis
Placental alkaline phosphatase Acid phosphatase Prostate specific antigen	Prostatic cancer	Useful in diagnosing stage and spread of tumor and in monitoring treatment

Hormones

Hcg (human chorionic gonadotropin)	Tumors of placenta; germ cell tumors of testis, sometimes ovary	Useful in diagnosing and monitoring patients
Polypeptide hormones (calcitonin, gastrin, somatostatin, serotonin, parathyroid hormone, pituitary hormones)	Endocrine tumors of various organs: thyroid, pancreas, gastrointestinal, and respiratory tracts, adrenal medulla, pituitary	Useful in tumor identification and classification, sometimes in monitoring patients
Epitactin (Ca1), milk factor epithelial membrane antigen	Antigens without specificity	Recognize cancer cell epitopes—not reliable
Hormone receptors: estrogen, progesterone	Breast cancer	Guide to therapy
	Endometrial cancer	Prognostic value still insecure
Growth factors, oncogene products, platelet-derived growth factor, insulin-like growth factor, nerve growth factor, epidermal growth factor	Widely distributed in many tumors	Have diagnostic value
		Prognostic value questionable except <i>c-myc</i> in neuroblastoma
Monoclonal antibodies recognizing specific organs or tumors (prostate, melanomas, ovarian tumors)	Various organs and tumors	Occasionally of diagnostic value
Monoclonal antibodies recognizing intermediate filaments	Widely distributed	Of value in diagnosis carcinoma vs sarcoma
Monoclonal antibodies recognizing stages of development of lymphocytes and their lineage (CDs, see Chap. 5)	Malignant lymphomas	Classification of lymphomas

Proliferation antigens	Ki67, PCNA (cyclin)	Possibly useful in tumor prognosis
* For further discussion see Chapter 45.		

It is quite evident that the issues of cell differentiation in cancer are extremely complex and **depend on multiple genes** that may or may not be expressed in any given cancer cell. There is, at this time, essentially no factual information on the molecular biologic mechanisms that account for the differentiation of cancer cells. On the other hand, a great deal of work has been performed to explain the mechanisms

P.175

of differentiation occurring during embryonal life of multicellular animals, when germ cells are organized to form tissues and organs. The best known target of these studies is a small worm, ***Caenorhabditis elegans***, which has been shown to carry 19,000 genes that have been sequenced. It is of interest that many genes that govern the embryonal development of the worm also occur in other multicellular organisms (Ruvkun and Hobert, 1998). It may be assumed that such developmental genes remain active in mature organisms and that they may be transmitted to cancer cells wherein they may be activated or inactivated according to circumstances about which nothing is known at this time. The proof that all genes are present in normal cells is provided by successful **animal cloning** using nuclei from mature cells inserted into the ovum.

MALIGNANCY-ASSOCIATED CHANGES

Under this name, Nieburgs et al (1967) described, many years ago, **changes observed in nuclei of leukocytes and epithelial cells in patients with cancer**. The changes were observed in cells that were either remote or adjacent to the site of cancer origin. The changes were classified as "orderly" with clear spherical areas in nuclear chromatin, or "disorderly," based on chromatin clumping. The orderly changes were observed in areas remote from the primary tumor and the disorderly changes were observed in cells adjacent to tumors.

The observations were revived by the observation that morphologically normal parabasal and intermediate squamous cells **in smears from patients with precancerous lesions of the uterine cervix** showed abnormal patterns of chromatin (Bibbo et al, 1981; Burger et al, 1981). These abnormalities could be measured and became the basis of an automated diagnostic system based on Feulgen-stained cells (Poulin et al, 1994). It is interesting that molecular biologic observations of morphologically normal epithelium, adjacent to cancer in various organs, may show genetic abnormalities. In practice, some degrees of nuclear atypia of benign epithelial cells may be observed in patients with various cancers, as will be discussed in appropriate chapter.

8

The Normal Female Genital Tract

ANATOMY

The female genital tract is composed of the vulva, the vagina, the uterus, the fallopian tubes, and the ovaries (Fig. 8-1).

Embryologic Note

The fallopian tubes, the uterus, and the adjacent part of the vagina are derived from two embryonal structures, the **müllerian ducts**, so named after Johannes Müller, a German anatomist of the early 19th century who first described them. The müllerian ducts fuse to become the uterus and the proximal vagina but remain separated to form the two oviducts (fallopian tubes). Imperfect fusion of the müllerian ducts results in formation of various degrees of duplication or subdivision of the uterus and the vagina, such as uterus septus and vagina septa. An excellent discussion of embryologic origin and congenital abnormalities of the female genital tract may be found in the book by Gray and Skandalakis (1972).

The Vulva

The vulva is the external portal of entry to the female genital tract. It is composed of two sets of **folds** or **labia** (from Latin, *labium* = lip; plural, *labia*), which frame both sides of the entrance to the vagina. The larger external folds, or **labia majora** (from Latin, *majus* = larger; plural, *majora*) are an extension

P.184

of the skin. The smaller inner folds, or **labia minora** (from Latin, *minor* = lesser; plural, *minora*), form a transition between the skin and the vagina. The outer surfaces of the labia minora retain some features of the skin, such as the presence of sebaceous glands, whereas the inner surfaces blend with the vagina. Located anteriorly between the labia minora is the female counterpart of the penis, the **clitoris**, provided with a retractile, prepuce-like structure. Located about 1 cm behind the clitoris is the opening of the **urethra**, the terminal portion of the urinary tract.

Figure 8-1 Schematic representation of the female genital tract in relation to bony structures (*upper left*); a coronal section (*lower left*); and a sagittal section showing the relationship to the bladder and the rectum (*right*).

The **lymphatic drainage** of the vulva is to the **inguinal lymph nodes**, which are the primary site of metastases in malignant tumors of the vulva.

The Vagina

In virgins, the entrance to the vagina is protected by a thin, perforated membrane, the **hymen**. The torn hymen persists in the form of small vestigial elevations at the entrance to the vagina. Just behind the vestigial hymen, on both sides of the posterior and lateral aspect of the vagina, there are two mucus-secreting glands, the glands of Bartholin or **Bartholin's glands**. During the childbearing age, the **adult vagina** is a canal, measuring approximately 10 cm in length, demarcated externally by the vulvar folds or labia, described above. The posterior end of the vagina is a blind pouch, the **cul-de-sac**. The anterior wall of the vagina, near the cul-de-sac, accommodates the uterine cervix. The area demarcated by the cervix and the blind end of the vaginal pouch is the **posterior vaginal fornix**. The fornix is quite deep and is the site wherein the secretions from the uterine glands, as well as exfoliated epithelial cells, accumulate. The wall of the vagina consists of three layers: the inner or mucosal layer of squamous epithelium, which shows transverse ridges or rugae. The mucosa is supported by a layer of smooth muscle. The thin outer serosal layer of the vagina is composed of connective tissue. The wall of the vagina is rich in lymphatic vessels. The **lymphatic drainage** of the anterior one-third of the vagina goes to the inguinal lymph nodes, whereas the posterior two-thirds drain into the pelvic lymph nodes.

Of importance are the **anatomic relationships of the vagina**, which are separated by thin connective tissue partitions or septa from the **rectum** posteriorly and the **bladder** anteriorly. Inflammatory processes and cancers of one of these organs may spread to the vagina and vice versa.

One of the rare but important congenital abnormalities of the vagina is **vagina septa**, in which the vagina, and possibly the uterus as well, is divided into two separate chambers. On

occasion, this is of significance in tumor diagnosis, since cancer may be present in one part of the genital tract while the healthy part is being investigated with negative results.

The Uterus

The uterus is arbitrarily divided into two parts—the **body, or corpus, and the neck, or cervix**. The corpus and the cervix usually form an angle of 120°, with the corpus directed anteriorly. The body or corpus of the uterus is a roughly pyramidal organ, shaped like an inverted pear and flattened in the anteroposterior diameter. In the resting stage, it measures 4 to 7 cm in length and approximately the same at its widest point. The apex of the pyramid, which becomes the cervix, is directed downward, whereas the wide base, or **fundus**, is directed upward. The cervix is a tubular structure measuring approximately 4 cm in length and about 3 cm in diameter. Of its total length, about half is within the vagina and is called the **portio vaginalis** (also known as **ecto- or exocervix**); the rest is embedded within the vaginal wall and is continuous with the body of the uterus.

The bulk of the uterus is formed by smooth muscle, or the **myometrium**, which is capable of a manifold increase in size and weight during pregnancy. The muscle encloses the **uterine cavity**, described below, and is covered on its surface by a reflection of the peritoneum, known as the **uterine serosa**. The uterus is anchored in the pelvis by a series of bands of connective tissue, or ligaments, the most important being the

P.185

posterior **round ligament**, and by folds or reflections of the peritoneum. Lateral folds, extending along the sides of the uterus and filled with loose connective tissue rich in lymphatics, are known as the broad ligaments forming the **left and the right parametrium** (plural, parametria).

The cervix has a very close anatomic relationship to the urinary bladder, which is anterior, and to both ureters, which run along the lateral walls of the cervix to reach the bladder. This anatomic arrangement explains the frequent involvement of the lower urinary tract by cervical cancer.

The Uterine Cavity

The thick, muscular walls of the uterus contain a cavity that, **within the cervix, is called the endocervical canal** and is continuous with the **endometrial cavity of the corpus**. The opening of the cervical canal into the vagina is referred to as the **external os** (from Latin, *os* = mouth). The point of transition of the endocervical canal into the endometrial cavity is known as the **internal os**. The endocervical canal is normally very narrow, measuring at the most 2 or 3 mm in diameter. The endometrial cavity follows the outline of the body of the uterus and is roughly conical, with the apex of the cone corresponding to the internal os and the base directed upward to the upper part, or **fundus**, of the uterine body. On each side of the triangular endometrial cavity, the horns, or the **cornua**, of the fundus are in communication with the **fallopian tubes**, or the oviducts. The lumen of the endometrial cavity in the resting stage is quite small, measuring only a few millimeters in the anteroposterior diameter. The endometrial cavity during pregnancy enlarges to harbor the fetus.

The Fallopian Tubes

The fallopian tubes (so named after Gabriello Fallopius, an Italian anatomist of the 16th century, who first described them), or the **oviducts**, measure between 8 and 12 cm in length and 3 and

5 mm in diameter. Their proximal ends are in direct continuation with the endometrial cavity, whereas their distal ends, with fingerlike **folds, or fimbriae**, open freely into the abdominal cavity, embracing the ovaries. The ova, released by the ovaries, find their way into the fallopian tubes, where they are fertilized by spermatozoa. The tubes are composed of three layers—the inner mucosal layer, followed by a layer of smooth muscle, and a serosal layer on the surface. A narrow canal, lined by the mucosa, is present throughout the entire length of the tube, thereby ensuring direct communication between the vagina and the abdominal cavity—a fact of some importance in the spread of infections and malignant tumors. The **histology** of the fallopian tubes is discussed in Chapter 15.

Ovaries

The ovaries are approximately ovoid structures, each measuring on the average 4 by 2 by 2 cm, located anatomically in the immediate vicinity of the abdominal or fimbriated end of the tubes, but not directly contiguous with the tubal lumens. In spite of this, the ova, formed in the ovary, find their way into the tubes and from there into the uterine cavity. The ovaries are loosely suspended, as are the tubes, by peritoneal folds. The histology of the ovaries is discussed in Chapter 15.

Adnexa and Lymphatic Drainage

The term **adnexa** or **uterine adnexa** is used to describe, as a single entity, the structures peripheral to the uterus, which consist of the fallopian tubes, ovaries, parametria, and regional lymph nodes. **The lymphatics of the uterus, the tubes, and the ovaries** are the tributaries of the pelvic and the aortic lymph nodes.

HISTOLOGY OF THE UTERUS

Cytologic examination of the female genital tract is based mainly on the study of epithelial cells, with cells of other derivation playing only a minor role. Three types of epithelia are present within the uterus and the vagina: (1) **the nonkeratinizing squamous epithelium** that lines the inner aspect of the labia minora of the vulva, the vagina, and the portio vaginalis of the cervix; (2) **the endocervical mucosa**; and (3) **the endometrium**. All these epithelia, but especially the endometrium and the squamous epithelium, are under hormonal influence. **The fullest development of these epithelia occurs during the childbearing age**, and our description will be based on their appearance at this time. Subsequently, the changes observed in prepubertal and postmenopausal women will be described. Further details on the histology of the vulva and vagina are provided in Chapter 15.

Nonkeratinizing Squamous Epithelium

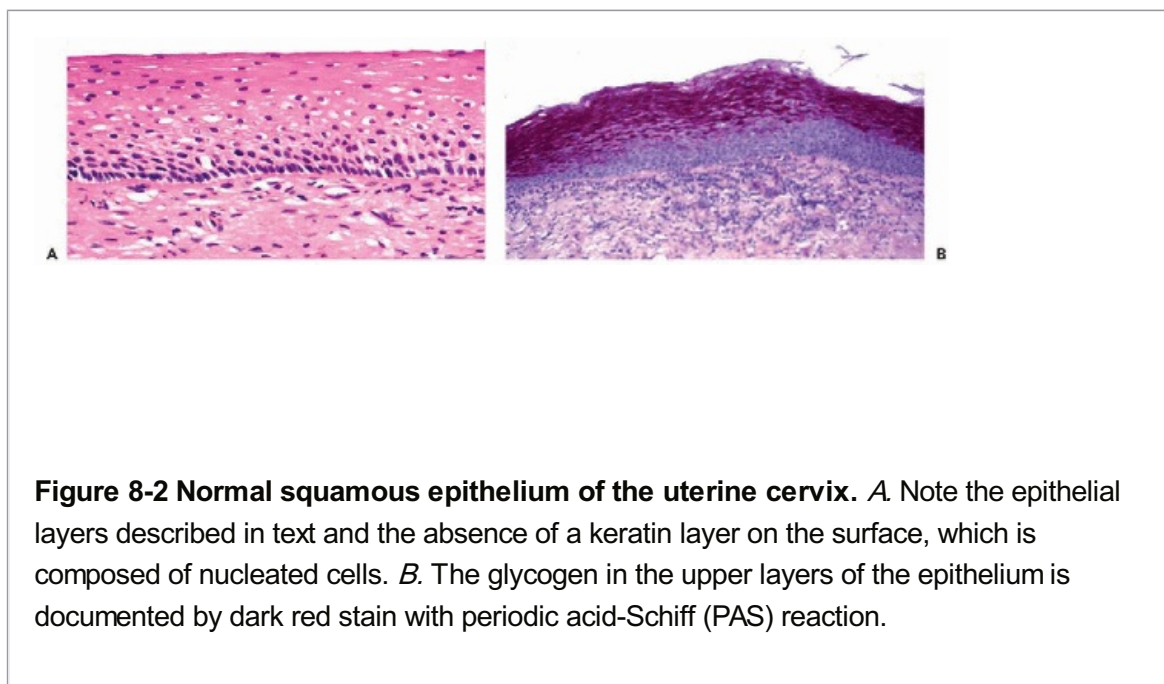

Squamous epithelium of the female genital tract is of two different **embryologic origins**. The epithelium lining the inner aspect of the labia minora and contiguous with the adjacent vagina, presumably to the level of the cervix, originates from the urogenital sinus. The remainder of the vaginal epithelium and the squamous epithelium of the vaginal portio of the cervix are derived from the müllerian ducts by **transformation (metaplasia) of the original cuboidal epithelium into squamous epithelium**. This fact has considerable bearing on certain congenital, neoplastic, and drug-induced abnormalities in the vagina and the cervix. The original squamous epithelium, not derived from metaplasia, is sometimes referred to as **native squamous epithelium**.

The fundamental structure of the squamous epithelium is described in Chapter 5 (see Fig. 5-4).

In the female genital tract, during sexual maturity, four layers or zones may be arbitrarily discerned and include the **bottom, or basal, layer**, which is the source of epithelial regeneration; the adjacent **parabasal zone**, imperceptibly blending with the **intermediate zone**, forming the bulk of the epithelial thickness; and the thin **superficial zone** (Fig. 8-2A). It is estimated that the process of squamous epithelial maturation

P.186

takes approximately 4 days. The process may be accelerated to 30 to 45 hours by the administration of estrogens. The mature **squamous epithelium of the cervix and vagina is rich in glycogen**, as documented by periodic acid-Schiff stain (Fig. 8-2B). Clinically, the presence of glycogen may be revealed by staining the squamous epithelium with Lugol's iodine solution, which, by binding with glycogen, stains the epithelium mahogany brown. This is the basis of **Schiller's test**, which serves to visualize nonstaining, pale areas of the epithelium suggestive of an abnormality that can be either benign or malignant.

The Epithelial Layers

The **basal, or germinative, layer** is composed of one row of small, elliptical cells, measuring approximately 10 μm in diameter. The vesicular nuclei, about 8 μm in diameter, commonly display evidence of active cellular growth, such as nucleoli or numerous chromocenters, and occasional mitoses. Under normal circumstances, the entire process of epithelial regeneration is confined to the basal layers; the remaining zones merely serving as stages of cell maturation.

The wide **midzone of the epithelium**, comprising the parabasal and intermediate layers, is composed of maturing squamous cells. As the maturation of the epithelium progresses toward the surface, the amount of cytoplasm per cell increases, whereas the sizes of the vesicular nuclei remain fairly constant, measuring about 8 μm in diameter. Arbitrarily, the two or three layers of smaller cells of the deeper portion of the midzone are designated as **parabasal layers**. The larger cells, adjacent to the superficial zone, form the **intermediate cell layers**. If further maturation is arrested under various circumstances, the midzone may form the surface of the squamous epithelium. The cells forming the bulk of the epithelium are bound to each other by welldeveloped desmosomal attachments or intercellular bridges (Fig. 8-3).

The **superficial zone** is composed of three or four layers of loosely attached cells that are still larger than intermediate cells. The nuclei of the cells forming the surface of the epithelium are considerably smaller and pyknotic, measuring about 4 μm in diameter. These cells are not capable of further growth. The most superficial cells of the squamous epithelium are cast off the epithelial surface by a mechanism known as **desquamation or exfoliation**. The exfoliation either pertains to single squamous cells or to cell clusters. Within the clusters, the cells are still bound by desmosomes, as shown by electron microscopy (Dembitzer et al, 1976). The desquamation (exfoliation) of the squamous cells is related to **splitting of the desmosomal bonds** and, presumably, other cell attachments by an unknown mechanism (Fig. 8-4). It must be noted that, in vitro, the disruption of desmosomes among exfoliated squamous cells by either proteolytic enzymes or mechanical means, without destruction of the cells, is exceedingly difficult. Hence, one can only speculate either that specific enzyme systems become activated in the superficial layers of the epithelium or that intracytoplasmic changes occur that weaken the desmosomes and thereby allow the superficial cells to be dislodged, presumably by the pressure exercised by the growing epithelium.

The squamous epithelium is provided with an **immune apparatus**, represented by bone marrow-derived modified macrophages or **dendritic cells**, which are dispersed in the basal and central layers. Among the dendritic cells are the **Langerhans' cells**, characterized by clear cytoplasm and vesicular nucleus. With special staining procedures, the branching cytoplasm of these cells can be identified (Figueroa and Caorsi, 1980; Roncalli et al, 1988). In **electron microscopy**, the cells are characterized by the presence of typical **cytoplasmic tennis racquet-shaped granules, known as Birbeck's granules** (Younes et al, 1968). Edwards and Morris (1985) studied the distribution of the Langerhans' cells in the squamous epithelium of the various parts of the female genital tract and found the highest concentration in the vulva and the lowest in the vagina. The Langerhans' cells play an important role in the **immune functions of the squamous epithelium**.

The development of a **superficial horny keratin layer composed of anucleated, fully keratinized cells**, as observed in the epidermis of the skin (see Chap. 5), does not normally take place in the female genital tract but may occur under abnormal circumstances (see Chap. 10). On the other hand, in a variety of conditions (e.g., pregnancy, menopause, hormonal deficiency, inflammation), the squamous

P.187

epithelium may **fail to reach its full maturity**. In such cases, the surface of the squamous epithelium may be formed by intermediate or, sometimes, parabasal layers.

Figure 8-3 Squamous epithelium of human uterine cervix. Electron micrograph of portions of two adjacent squamous cells from epithelial midzone. There are numerous cytoplasmic filaments, many ending in desmosomes (D). Rich deposits of glycogen (G) are observed adjacent to the nucleus (N). The empty areas within the glycogen zone are due to partial dissolution of glycogen in the fixative (glutaraldehyde). A few vesicles are present between the nuclear membrane and the glycogen zone. A nucleolus (NL) is also noted. (×9,000.)

Basement Membrane and the Supporting Apparatus

Immediately underneath the basal layer of the epithelium, there is a thin band of hyaline material that is quite dense optically and is referred to as the **basement membrane**; it can also be found underneath the endocervical surface epithelium and glands (see Chap. 2). The significance of the basement membrane in determining invasion of a cancer is discussed in Chapters 11 and 12.

Figure 8-4 Electron micrograph of the superficial layer of the squamous epithelium of the vagina. Breakage of a desmosome (*arrow*) is shown next to two still intact desmosomes. ($\times 33,000$.) (Photo by Dr. H. Dembitzer, Montefiore Hospital and Medical Center, New York, NY.)

Beneath the basement membrane, there is a **connective tissue stroma**, containing variable numbers of **T and B lymphocytes**, with the highest concentration in the transformation

P.188

zone (Edwards and Morris, 1985). Small, fingerlike, **blood vessel-bearing** projections of connective tissue (**papillae**) supply the epithelium with nutrients.

Electron Microscopy

Transmission electron microscopy discloses a multilayer epithelium with cells bound to each other by numerous desmosomes. The cytoplasm is rich in glycogen and tonofibrils (see Fig. 8-3). In the most superficial epithelial layers, breakage of desmosomes is evident (Fig. 8-4) and accounts for spontaneous shedding of the superficial cells.

Scanning electron microscopy of the surface of the normal squamous epithelium discloses platelike arrangement of large squamous cells closely fitting with each other (Ferenczy and Richart, 1974). The surface of the cells is provided with a network of short uniform microridges. At the points of cell junctions, more prominent ridges may be noted (Fig. 8-5).

Endocervical Epithelium

The epithelial lining of the endocervical canal, and of the endocervical glands, is formed by a single layer of **mucus-producing tall columnar cells** with oval nuclei and clear cytoplasm, also known as **picket cells** (Fig. 8-6). The endocervical epithelium **participates in the events of the menstrual cycle**, described below, and this is reflected by the consistency of the

endocervical mucus. During the **preovulatory phase of the cycle, the mucus is thick and readily crystallized**; it becomes **liquid just before and during the ovulation**, presumably to facilitate the entry of spermatozoa into the uterine cavity. Consequently, the appearance of the cytoplasm of the endocervical cells and the position of nuclei depends on the phase of the menstrual cycle. During the **proliferative phase**, the cytoplasm is opaque and the nuclei are centrally located (Fig. 8-6A). During the **secretory phase**, the transparent cytoplasm is bulging with accumulated mucus that pushes the flattened nuclei to the basal periphery of the cells (Fig. 8-6B). In such cells, the luminal surface is flat but may show tiny droplets or smudges, reflecting secretion of mucus. The **nuclei** of the normal endocervical cells are open (vesicular) and spherical, and measure approximately 8 μm in diameter. **Ciliated cells** are commonly present in the upper (proximal) segment of the endocervical canal, as confirmed in a careful study by Babkowski et al (1996). The nuclei of the ciliated cells are somewhat larger than those of nonciliated cells (see Figs. 8-19B and 8-20D). Located among the columnar cells at the base of the epithelium, adjacent to the basement membrane, there are small, triangular **basal, or reserve, cells**. These cells are very difficult to see in light microscopy of normal epithelium but have been clearly demonstrated by electron microscopy. Under abnormal circumstances, a hyperplasia of the reserve cells may be observed. The role of reserve cells as the cell of origin of squamous metaplasia of the endocervix is discussed in Chapter 10.

Figure 8-5 Scanning electron micrographs of mature squamous epithelium of the portio of the uterine cervix. *A*. Low-power view showing platelike, flat, superficial cells of various sizes. The points of junction of these cells are marked by ridges. A tear, suggestive of cell exfoliation, is seen on the right. *B*. Detail of the surface showing an interlacing network of microridges characteristic of mature squamous cells. In the right upper corner of the photograph, a more prominent ridge marks the point of junction with an adjacent superficial squamous cell. (*A*: High magnification; *B*: $\times 10,000$.) (From Ferenczy A, Richart RM. Scanning electron microscopy of the cervical transformation zone. *Am J Obstet Gynecol* 115:151, 1973.)

The endocervical glands are of the simple tubular branching type, and they may vary substantially in number and distribution. In some women, the normal glands may be situated

deeply within the wall of the cervix, at a considerable

P.189

distance from the surface; this distribution of endocervical glands is of importance in the diagnosis of extremely well-differentiated endocervical adenocarcinoma (see Chap. 12). The presence of glands underneath the squamous epithelium of the portio, in the area of the external os (transformation zone), is normal. The epithelium lining the glands is identical to the surface epithelium.

Figure 8-6 Normal endocervix. *A.* Typical columnar epithelium lining the surface of the endocervical canal and the endocervical glands. *B.* Higher power view of endocervical lining epithelium, composed of "picket cells" with clear cytoplasm, corresponding to the secretory phase of the menstrual cycle.

Electron Microscopy

Transmission electron microscopic studies of the endocervical epithelium reveal typical, mucus-secreting cells with secretory granules in the cytoplasm. On the luminal surface, the cells are bound to each other by junctional complexes and, elsewhere, by desmosomes (Fig. 8-7). The basal reserve cells are readily observed at the base of the columnar endocervical cells.

Figure 8-7 Electron micrograph of endocervical epithelium. At *left* there is a mucus-secreting cell, characterized by a large number of cytoplasmic granules (M); at *right* a ciliated epithelial cell is seen (see Fig. 8-8). ($\times 13,000$.) (Photo by Dr. H. Dembitzer, Montefiore Hospital and Medical Center, New York, NY.)

Scanning electron microscopy shows that ciliated endocervical cells are more common than is generally estimated by light microscopy (Fig. 8-8).

Transformation Zone or the Squamocolumnar Junction

The area of the junction between the squamous and the endocervical epithelium is of considerable importance in

P.190

the genesis of carcinoma of the uterine cervix (see Chap. 11). In a normal, quiescent cervix, the transition between the two epithelial types is often sharp and is known as the **squamocolumnar junction**, now usually designated as **the transformation zone** (Fig. 8-9). The term **transformation zone** is based on colposcopic observations of adolescent and young women, documenting that the glandular epithelium of the cervix in the area of the squamocolumnar junction is undergoing constant metaplastic transformation into squamous epithelium. The events of transformation are sometimes reflected in cervical smears, showing side by side endocervical glandular cells and young metaplastic squamous cells.

Figure 8-8 Scanning electron micrograph of endocervical epithelium. Numerous ciliated cells are next to mucus-secreting cells (M). The latter are characterized by a shaggy configuration of the surface (see Fig. 8-7). ($\times 4,800$.) (Courtesy of Dr. Ralph Richart, New York, NY.)

The anatomic location of the transformation zone varies considerably and is age-dependent (Fig. 8-10). In **adolescents and young women**, the junction is usually located at the level of the external os, but may extend to the adjacent vaginal aspect of the uterine cervix. In the latter case, the area occupied by the endocervical epithelium on the surface of the cervix may be visible to the naked eye as a sharply demarcated red area, sometimes inappropriately called an **erosion**, but better designated as **eversion, ectropion, or ectopy**. The redness reflects the presence of blood vessels under the thin endocervical epithelium. The ectropion is a benign, self-healing condition, which, however, may mimic important lesions of the cervix. The cytologic presentation and clinical significance of the ectropion are discussed in Chapter 9.

With advancing age, the junction tends to move up into the endocervical canal. At the time of the menopause, the junction is usually located within the endocervical canal and is hidden from view.

Because most of the initial precancerous changes in the uterine cervix occur within the transformation zone, this is an area of major importance in cervix cancer prevention (see Chap. 11). For this reason, much emphasis has been placed on sampling of the transformation zone by cervicovaginal smears (see comments on smear adequacy at the end of this chapter). It is evident that the transformation zone is more readily accessible in younger than in older women. For comments on cytology of the transformation zone, see below.

The Endometrium

The transition between the endocervical epithelium and the endometrium usually occurs at the

level of the internal os. The transition between the large picket cells of the endocervical mucosa and the smaller cells of the endometrium is usually quite sharp.

The endometrium is essentially composed of layers of **surface epithelium composed of cuboidal cells**, forming simple **tubular glands, surrounded by stromal cells**. During the childbearing age, the endometrium undergoes **cyclic changes (menstrual cycle)** to prepare it for the implantation of the fertilized ovum, hence for pregnancy. The appearance of the glands and the stroma changes with the phase of the cycle, as described below. If the implantation

P.191

does not occur, the endometrium is shed before the beginning of the next menstrual cycle. A detailed history of the cyclic changes and their hormonal background can be obtained elsewhere; for our purpose, only a brief summary is necessary.

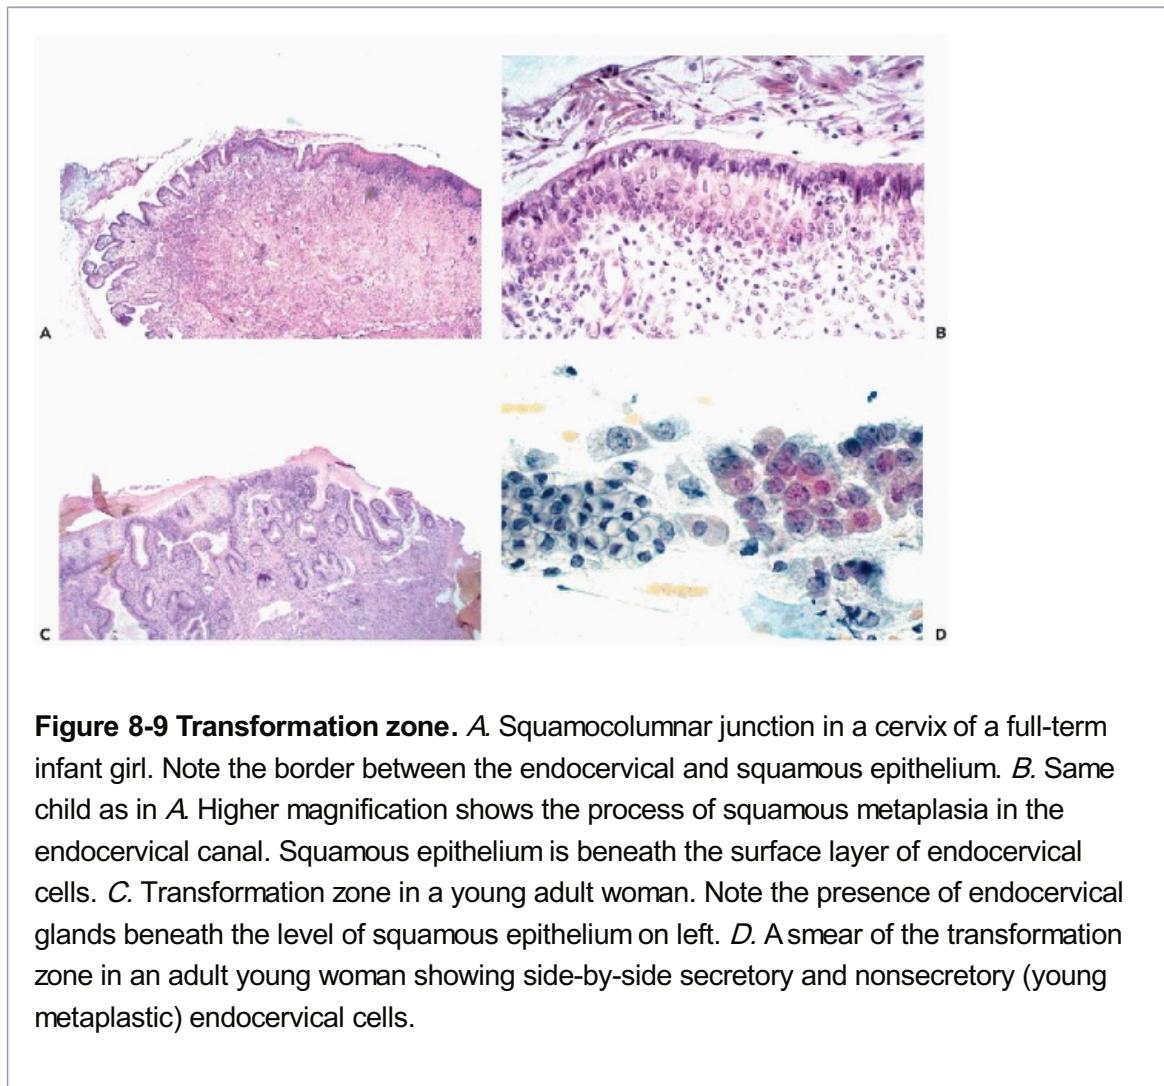

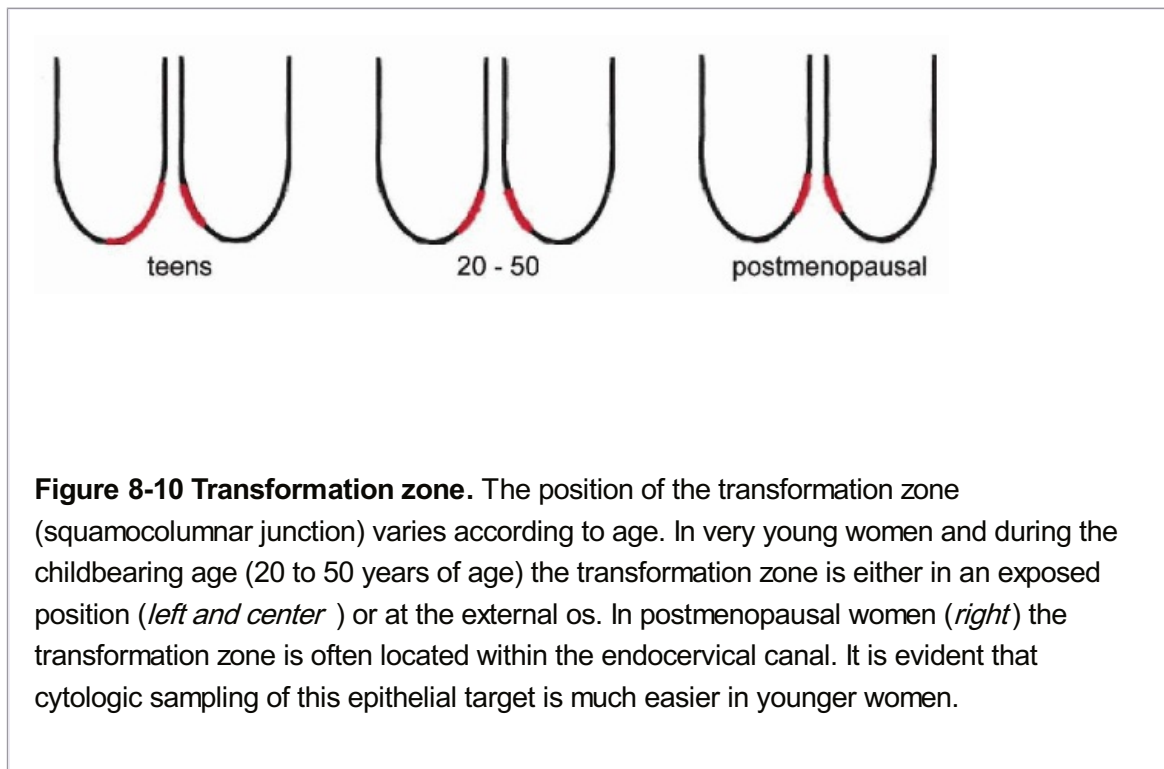

Figure 8-9 Transformation zone. *A.* Squamocolumnar junction in a cervix of a full-term infant girl. Note the border between the endocervical and squamous epithelium. *B.* Same child as in *A.* Higher magnification shows the process of squamous metaplasia in the endocervical canal. Squamous epithelium is beneath the surface layer of endocervical cells. *C.* Transformation zone in a young adult woman. Note the presence of endocervical glands beneath the level of squamous epithelium on left. *D.* A smear of the transformation zone in an adult young woman showing side-by-side secretory and nonsecretory (young metaplastic) endocervical cells.

The Endometrium During the Menstrual Cycle

The menstrual cycle is the result of a sequence of hormonal influences that, in a normal woman, follow each other with great regularity from puberty to menopause, except during pregnancy. It has been shown by Frisch and McArthur (1974) that a certain minimal body weight in relation to height is necessary for the onset and maintenance of the menstrual activity. The ovarian hormones most directly responsible for the menstrual cycle are **estrogen**, produced by follicles that harbor ova, and **progesterone**, produced by corpus luteum that forms after expulsion of the ovum. The ovarian activity is regulated by hormones produced by the anterior

lobe of the pituitary and the hypothalamus. A simple diagram summarizes the principal hormonal factors and their influence on the endometrium (Fig. 8-11).

Menstrual Bleeding

The beginning of the menstrual flow marks the **first day of the cycle**. It corresponds to disintegration and necrosis of the superficial portion of the endometrium, indicating

P.192

the end of the activity of progestational hormones originating in the ovarian corpus luteum. The casting off of the endometrium usually takes 3 to 5 days and is accompanied by bleeding from the ruptured endometrial vessels.

Figure 8-11 A diagrammatic and greatly simplified representation of the influence of anterior pituitary and ovarian functions on the cyclic growth and disintegration of endometrium.

Proliferative Phase

Endometrial necrosis is followed by regeneration and the onset of the growth or proliferative phase, during which the endometrium grows in thickness. This phase of endometrial growth is **under the influence of estrogens originating in the granulosa and theca cells** of the ovarian follicles and, in essence, is a preparation for pregnancy. The **initial event** is the **regeneration of the surface epithelium** from residual endometrial glands. During this stage, the endometrial **surface epithelium** is composed of cuboidal to columnar cells with scanty cytoplasm and spherical, intensely stained nuclei that show significant mitotic activity. Occasionally, larger cells with clear cytoplasm (helle Zellen of the Germans) are also present. Their significance is unknown.

Figure 8-12 Histology of endometrium. *A.* Early proliferative phase. The glands are small, lined by cuboidal cells showing mitotic activity. *B.* Early secretory phase. The large, convoluted glands are lined by larger cells with subnuclear vacuoles.

The glands of the proliferative phase are formed by **invagination of the surface epithelium**. The glands are straight tubular structures lined by one or two layers of cuboidal, sometimes columnar, cells with scanty cytoplasm and intensely staining nuclei that show intense mitotic activity. The endometrial stroma in this stage is compact and formed by small cells (Fig. 8-12A). Single **ciliated cells** may be observed in proliferative endometrium, mainly on the surface.

Ovulation and the Secretory Phase

The release of the ovum from the ovarian follicle (ovulation) usually occurs between the 11th

and 14th days of a 28-day

P.193

menstrual cycle and signals the onset of the secretory phase. The ovarian corpus luteum, which replaces the follicle, begins to function by secreting progesterone, which stimulates the secretory activity of the cells lining the endometrial glands. **Secretory vacuoles**, composed mainly of **glycogen**, are formed, at first in subnuclear position, later shifting to a supranuclear one, closer to the lumen of the gland. At the same time, the straight tubular glands become more tortuous, and the surrounding **stromal cells** become larger and eosinophilic, resembling decidual cells (Fig. 8-12B). There is evidence that the actual process of secretion is of the apocrine type; that is, the apical portions of the glandular cells containing glycoproteins are cast off into the lumen of the gland. With the passage of time, the tortuosity of the glands and the vacuolization of the lining cells continue to increase and the stroma becomes loosely structured. Just before the beginning of the next menstrual flow, the glands acquire a **see-saw appearance** before collapsing, signaling the onset of the epithelial necrosis and the beginning of a new cycle.

Figure 8-13 Electron micrograph of proliferative endometrium. View of an acinus of an endometrial gland showing cilia-forming columnar cells. The cytoplasm, although rich in a variety of organelles, shows no distinguishing features. The nuclei (N), some containing two nucleoli, are not remarkable. ($\times 7,500$.) (Courtesy of Prof. Claude Gompel, Brussels, Belgium.)

Electron Microscopy

Transmission electron microscopic studies of human endometrium in various phases of the cycle were carried out by several investigators. In the proliferative phase, the glands are composed of columnar cells, some ciliated, resting on a basement membrane. These cells have no distinguishing features (Fig. 8-13). The secretory phase is accompanied by a rapid formation of **deposits of glycogen**, which is the chief product of the glandular cells. Accumulation of glycogen and glycoproteins in the secretory phase is accompanied by formation of large mitochondria with peculiar cristae arranged in parallel fashion (Fig. 8-14) (Gompel, 1962, 1964).

Scanning electron microscopic studies disclosed some differences between the epithelium of the endometrial surface and that of the endometrial glands. The endometrial surface epithelium shows few cyclic changes. The cells produce cilia and show relatively little secretory activity during the secretory part of the cycle. The epithelium lining the endometrial glands during the proliferative phase shows an intense production of cilia and microvilli. During the secretory

P.194

phase, the formation of cilia is inhibited, and, under the influence of progesterone, there is conversion of the glandular cells to the secretory function (Ferenczy, 1976; Ferenczy and Richart, 1973).

Figure 8-14 Electron micrograph of secretory endometrium. Glycogen deposit (G), seen as an accumulation of black granules, and large mitochondria (M) with parallel cristae

are well in evidence. ($\times 18,500$.) (Courtesy of Prof. Claude Gompel, Brussels, Belgium.)

NORMAL CYTOLOGY OF THE UTERUS DURING CHILDBEARING AGE

Cells Originating from Normal Squamous Epithelium

Superficial Squamous Cells

During the childbearing age of a normal woman, the bulk of cells observed in cervicovaginal smears originate from the superficial zone of mature squamous epithelium. Although several varieties of cells may originate from the surface of the squamous epithelium, the term **superficial squamous cells** is reserved for large **polygonal** cells possessing a **flat, delicate, transparent cytoplasm** and **small, dark nuclei, averaging about 4 μm in diameter** (Figs. 8-15A,B). The diameter of the superficial squamous cells is approximately 35 to 45 μm but somewhat smaller, or more often, larger cells may occur. The polygonal configuration of these cells reflects the rigidity of the cytoplasm, caused by the presence of numerous bundles of tonofibrils (intermediate filaments) seen in transmission electron microscopy (see previous). Scanning electron microscopy emphasizes the irregular configuration of these cells (Fig. 8-16). The flat surface, provided with microridges, shows a knoblike elevation of the spherical nucleus.

In well-executed Papanicolaou stains, **the cytoplasm** of the majority of the superficial cells stains predominantly a

P.195

delicate pink. This staining property reflects the chemical affinity of the cytoplasm for acid dyes such as eosin; hence, the term **eosinophilic**, or a less frequently used term, **acidophilic cytoplasm**. Dryness and exposure to air tend to enhance the eosinophilic properties of cells. The cytoplasm of the superficial cells may, at times, stain a pale blue, reflecting a slight affinity for basic dyes such as hematoxylin. Intense blue staining (cyanophilia) of the cytoplasm of superficial cells should not be seen in Papanicolaou stain, although it may be seen with other staining procedures such as the Shorr's stain (see Chap. 44).

Figure 8-15 Superficial and intermediate squamous cells. *A.* Mature squamous cells with tiny, pyknotic nuclei, surrounded by a narrow clear zone. Some of the cells contain small, dark, brown cytoplasmic granules. *B.* Superficial and intermediate squamous cells, the latter with blue cytoplasm and larger, vesicular nuclei. *C.* "Polka dot cell." A poorly preserved superficial squamous cell at higher magnification, showing brown granules of various sizes in the cytoplasm. *D.* Nuclear bar (*arrow*) in intermediate squamous cell.

Small, dark brown cytoplasmic granules are often visible, usually in a perinuclear location but, occasionally, they are also present in the periphery of the cytoplasm (see Fig. 8-15A). Masin and Masin (1964) documented that the granules contain lipids and that their presence is estrogen dependent. Occasionally, **larger, spherical, pale brown inclusions** of variable sizes may be observed in the cytoplasm of the superficial squamous cells, which have been named **polka-dot cells** (Fig. 8-15C). The nature of these inclusions is unknown. Some observers consider such cells to be an expression of human papillomavirus (HPV) (summary in DeMay, 1996). In our experience, such inclusions are uncommon and occur mainly in poorly preserved or degenerated squamous cells. The polka dot cells do not correspond to any known disease state, a view also shared by Schiffer et al (2001). Superficial squamous cells with **vacuolated cytoplasm, resembling fat cells**, have also been considered by some as reflecting HPV infection. In our experience, such cells are usually the result of treatment by radiotherapy or cautery (see Chap. 18).

The superficial squamous cells are the end-of-the-line dead cells and this is reflected in their small **nuclei**, which are **pyknotic**, that is, the nuclear material has become condensed and shrunken. A **narrow clear zone** often surrounds the condensed nucleus, indicating the area occupied by the nucleoplasm before shrinkage (see Fig. 8-15A,B). Sometimes the nuclear chromatin may be fragmented and broken into small granules, suggestive of **karyorrhexis** and, hence, **apoptosis** (see Chap. 6). Upon close inspection of such cells, minute detached fragments of nuclear material may be seen in the vicinity of the main nuclear mass. In phase microscopy, the pyknotic nuclei display a characteristic reddish hue.

Since complete maturity of the epithelium can rarely occur in the absence of estrogens, **nuclear pyknosis in mature**

P.196

superficial cells constitutes morphologic evidence of estrogenic activity. This feature is of value in the analysis of hormonal status of the patient (see Chap. 9).

Figure 8-16 Scanning electron micrograph of a cluster of superficial squamous cells from the uterine cervix. The flat surface of the cells provided with microridges and a knoblike, elevated nucleus may be seen. More prominent ridges mark the cell junctions. (Approximately $\times 2,500$.) (Courtesy of Dr. Ralph Richart, New York, NY.)

Intermediate Squamous Cells

The intermediate-type cells are of the same size as the superficial cells or somewhat smaller. Their cytoplasm is usually basophilic (cyanophilic) and occasionally somewhat more opaque in the Papanicolaou stain, although eosinophilic cells of this type may occur. The **chief difference between the superficial and the intermediate cells lies in the structure of the nucleus**; the nuclei of the intermediate cells measure about $8\text{ }\mu\text{m}$ in average diameter, are spherical or oval, with a clearly defined nuclear membrane surrounding a well-preserved homogeneous, faintly granular nucleoplasm. Chromocenters and sex chromatin may be observed within such nuclei. The term **vesicular nuclei** is applied to define this type of nuclear configuration.

It is not uncommon to observe in the nuclei of normal intermediate cells **nuclear grooves or creases** in the form of straight or branching dark lines (review in Payandeh and Koss, 2003). In some cases, **chromatin bars** with short lateral extensions (**caterpillar nuclei**), are observed

along the longer axis of oval nuclei (Fig. 8-15D). Such bars are commonly observed in the nuclei of squamous cells in oral and conjunctival smears, discussed in Chapters 21 and 41. Kaneko et al (1998) suggested that the nuclear creases or bars represent an infolding of the nuclear membrane but the mechanism of their formation remains unknown. It has been documented that the presence or frequency of nuclear grooves is not related to either inflammatory or neoplastic events (Payandeh and Koss, 2003).

A **variant of the intermediate** cells is the boat-shaped **navicular cell** (from Latin, *navis* = boat). These approximately oval-shaped cells store **glycogen in the form of cytoplasmic deposits** that stain yellow in Papanicolaou stain, and push the nucleus to the periphery (see Figs. 8-27B and 8-31A). The navicular cells are commonly seen in pregnancy and may be observed in early menopause (see below).

It must be emphasized that, under a variety of physiologic and pathologic circumstances (pregnancy, certain types of menopause, hormonal deficiencies, inflammation), the **squamous epithelium of the female genital tract may fail to reach full maturity**. In such cases, the intermediate, or sometimes even parabasal cells, form the epithelial surface and become the preponderant cell population in smears (see below and Chap. 9).

Physiologic Variations of the Superficial and Intermediate Squamous Cells

Cytoplasmic folding, often accompanied by **clumping** of cells is a normal phenomenon occurring during the last third of the menstrual cycle, prior to the onset of menstrual bleeding. Cytoplasmic folding may also occur during pregnancy (see below). Folding and clumping are often accompanied by lysis of the cytoplasm (cytolysis) caused by lactobacilli (see below; see also Fig. 8-31B).

The superficial and intermediate cells may form **tight whorls or “pearls”** in which the cells are concentrically arranged, in an onion-like fashion (Fig. 8-17A,B). The

P.197

whorls are often interpreted as reflecting estrogenic effect, but the proof of this is lacking. This must be differentiated from a similar arrangement of cells with abnormal nuclei, occurring in squamous carcinoma (see Chap. 11). An elongation of the intermediate cells, resulting in a **spindly shape**, has been observed at times (Fig. 8-17C). Such cells may somewhat resemble smooth-muscle cells (see Fig. 8-36). The identification of spindly squamous cells is facilitated in the presence of transitional forms of these cells, as shown in Figure 8-17C. Benign spindly squamous cells must also be differentiated from similarly shaped cancer cells with abnormal nuclei (see Chap. 11).

Figure 8-17 Benign squamous pearls and spindly squamous cells in cervical smear. *A.* Note the small nuclei in the whorls of keratin-forming cells. *B.* Cervix biopsy from the same patient showing pearl formation within the benign squamous epithelium (*arrow*). *C.* Spindly small intermediate squamous cells. Note normal nuclei.

Parabasal Cells

The parabasal squamous cells vary in size and measure from 12 to 30 μm in diameter. The nuclei are vesicular in type and similar to the nuclei of intermediate squamous cells. The frequency of occurrence and the **morphologic presentation** of parabasal squamous cells in cervicovaginal smears **depend on the technique of securing the sample**.

In vaginal pool smears obtained by a pipette or a blunt instrument, **spontaneously exfoliated parabasal cells occur singly and are usually round or oval in shape, with smooth cytoplasmic borders** (Fig. 8-18A). The cytoplasm is commonly basophilic (cyanophilic) and occasionally contains small vacuoles. Exposure to air and dryness may cause

cytoplasmic eosinophilia. The **nuclei are usually bland and homogeneous**. This appearance of parabasal cells results from contraction of the cytoplasm following cell death and breakage of desmosomes that occurred prior to desquamation. Few cells of this type are seen in normal smears from women in their 20s and early 30s, but the number increases in women more than 35 years of age. Such cells may become the **dominant cell type in postmenopausal women** with epithelial atrophy (see below). In the presence of **inflammatory processes** within the vagina or the cervix with resulting damage to the superficial and intermediate layers of the squamous epithelium, the proportion of parabasal cells in smears **may increase substantially** (see Chap. 10).

In direct cervical scrapes and brush smears, the proportion of parabasal cells is much higher than in vaginal pool smears. Such cells are derived from areas of **immature squamous epithelium** and **areas of squamous metaplasia** of the endocervical epithelium in the transformation zone and the endocervical canal. For further discussion of squamous metaplasia (see Chap. 10). In cervical scrape smears, such cells are **trapped in streaks of endocervical mucus**. In preparations obtained by endocervical brushes and in preparations obtained from liquid fixatives, the relationship of parabasal cells to endocervical mucus is lost.

Parabasal cells forcibly dislodged from their epithelial setting by an instrument are often angular and have irregular polygonal shapes. Such cells occur singly, but often form flat clusters that vary in size from a few to several hundred cells. In clusters, such cells often form a **mosaic-like pattern**, in which the contours of the cells fit each other (Figs. 8-9D and 8-18B). The term **metaplastic cells** is often used to describe such cells, although their origin from squamous metaplasia is not always evident or secure. The reason for the angulated appearance of parabasal cells is the presence of intact desmosomes that bind the adjacent cells together. As the cytoplasm shrinks during the fixation process, the desmosomes are not affected and, consequently, the portions of the cytoplasm attached to the desmosomes stretch and become elongated, giving the cells an angulated appearance (see Fig. 8-18B). Thus, **the angulated appearance of the parabasal cells of “metaplastic” type, whether occurring singly or in clusters, is a useful fixation artifact.**

Figure 8-18 Parabasal and basal squamous cells. *A.* Parabasal cells from a cervicovaginal smear. Many of these small cells are spherical in shape, have a basophilic cytoplasm and spherical nuclei. *B.* Parabasal cells from a direct cervical sample. The angulated appearance of these cells suggests origin from the transformation zone. Such cells are usually classified as metaplastic. *C.* Basal cells in a brush specimen. A cohesive cluster of very small epithelial cells with very scanty cytoplasm and small nuclei of identical sizes. It may be assumed that these cells are basal squamous cells. The finding is uncommon.

The nuclei of parabasal cells, which measure about 8 μm in diameter, show a **fine network of chromatin, chromocenters**, and, occasionally, **very small nucleoli**. When compared with superficial or intermediate cells, the nuclei of parabasal cells occupy a much larger portion of the total cell volume and, therefore, give the erroneous impression of being larger. I have not observed mitotic figures among normal parabasal cells in smears.

The presence of parabasal cells in smears is of interest in defining an “**adequate cervical**

smear,” which is often judged by the presence of “metaplastic” cells derived from the transformation zone and the endocervical canal (for further discussion of smear adequacy, see end of this chapter). It is evident that when the transformation zone is readily accessible to sampling, as in women of childbearing age, it will be better represented in the smears than in older women (see Figs. 8-9D and 8-10).

Basal Cells

Because of their protected status, the basal cells are practically never seen in smears. If present, it may be safely assumed that a pathologic process or vigorous brushing has damaged the upper layers of the squamous epithelium, resulting in the appearance of these very small round or oval cells, resembling miniature parabasal cells. Their very scanty cytoplasm is basophilic but may become eosinophilic in dry smears (Fig. 8-18C). The nuclei are of the same size as those of the parabasal cells but, because of the small size of the cells, appear to be larger. The nuclei display fine chromatin structure with chromatin granules and, occasionally, tiny round nucleoli. **The uncommon normal basal squamous cells should not be confused with small cancer cells that may be of similar size and configuration** (see Chap. 11).

Dendritic Cells and Langerhans Cells

These cells have never been identified by us in normal smears, although their presence in the histologic sections of the squamous epithelium has been well documented, as previously described.

Cells Originating from the Endocervical Epithelium

In **vaginal pool smears**, the endocervical cells are relatively uncommon and rarely well preserved. In **cervical smears** obtained by means of instruments, particularly endocervical brushes, the endocervical cells are usually numerous and well preserved. **When seen in profile, the endocervical cells are columnar** and measure approximately 20 µm in length and from 8 to 12 µm in width (Fig. 8-19A). Shorter cells, of plump, more cuboidal configuration may also occur. The columnar endocervical cells may occur singly but, quite often, they are seen as sheets of parallel cells, **arranged in a palisade** (Fig. 8-19B). When the endocervical cells are flattened on the slide and are seen “on end,” they form **tight clusters or plaques**, wherein the cells form a tightly fitting mosaic resembling a **honeycomb**. In such plaques, the cell membranes form the partitions of the honeycomb and the centers are filled by clear cytoplasm surrounding the nuclei (Fig. 8-19A,C). The identification of such cells as endocervical is facilitated if columnar cells are present at the periphery of the cluster.

The cytoplasm of endocervical cells is either finely vacuolated or homogeneous and faintly basophilic or distended by clear, transparent mucus that is pushing the nuclei toward

P.199

the narrow end of the cell. Some such cells may become nearly spherical in shape because of cytoplasmic distention by mucus. On the surface of the mucus-containing cells, small droplets or smudges of mucus may be observed.

Figure 8-19 Endocervical cells. *A.* Two of the most characteristic presentations of endocervical cells in cervical smears are a strip of palisade-forming columnar cells with opaque cytoplasm and a cluster of such cells seen “on end,” forming a “honeycomb pattern” wherein the borders of adjacent cells are clearly seen. In the palisading cluster, the surface of the cells is topped with a pink layer of mucus. *B.* Higher-power view of endocervical cells with clear cytoplasm. Some of the nuclei contain tiny nucleoli. *C.* A flat “honeycomb” cluster of endocervical cells with clear cytoplasm. The irregularly shaped nuclei show short, dense protrusions or “nipples.”

The nuclei are spherical or oval, vesicular in configuration, with delicate chromatin filaments, often showing chromocenters and very small nucleoli. The **nuclei may vary in size**. The **dominant size of the nuclei is about 8 μm in diameter** but larger nuclei, up to 15 or 16 μm in diameter, are not uncommon. The variability of the nuclear sizes may reflect stages in cell cycle or other, unknown factors. **Multinucleated cells** may also occur (Fig. 8-20A). The fragile cytoplasm of the endocervical cells may disintegrate, with resulting **stripped, or naked, nuclei**,

usually of spherical or somewhat elliptical configuration (Fig. 8-20B). These nuclei may also vary in size and may be difficult to recognize, unless they are similar to, or identical with, the nuclei of adjacent better-preserved endocervical cells. Small **intranuclear cytoplasmic inclusions** in the form of clear areas within the nucleus may occur in endocervical cells (Fig. 8-20B).

At the time of ovulation, and sometimes during the secretory (postovulatory) phase of the menstrual cycle, the nuclei of endocervical cells form **intensely stained, dark, nipplelike protrusions** of various sizes, up to 3 μm in length, that are an extension of the nucleus into the adjacent cytoplasm (see Figs. 8-19C and 8-20C). The protrusions appear mainly on the luminal aspect of the nucleus, facing the endocervical lumen. Sometimes the protrusions are split in two. All stages of formation of the protrusions may be observed, ranging from a thickening of the nuclear membrane to protrusions growing in size. In nuclei with fully developed protrusions, the remainder of the nucleus is usually less dense and transparent, suggesting that there has been a shift of the chromatin to the protrusion. The mechanism of formation and the nature of the protrusions are the subject of a considerable debate. Taylor (1984) thought that the **protrusions occurred mainly in ciliated endocervical cells** and that their formation was the result of high ciliary activity. McCollum (1988) observed the protrusions in women receiving the long-term contraceptive drug medroxyprogesterone, during periods of amenorrhea, when the estrogenic activity was low. McCollum thought that the protrusions represented an **attempt at nuclear division arrested by progesterone and, therefore, consistent with events occurring at the onset of ovulation**. Zacharopoulos et al (1998) studied the protrusions by a number of methods, including electron microscopy, cytochemistry, and in situ hybridization of X chromosome. These investigators observed the presence of **nucleoli and single X chromosome within the protrusions** and reported findings suggestive of **formation of an abortive mitotic spindle** attached to the protrusion, thus providing support to McCollum's suggestion that the protrusion represents an attempt at mitotic division. Although further studies may shed some additional light on this very interesting phenomenon, it is quite certain that the protrusions **do not represent an artifact**, as has been suggested by Koizumi (1996). It is of note that **similar protrusions** may be occasionally observed in histologic sections of the endocervix during the secretory phase of the cycle **and in epithelial cells of various origins**, for example, in bronchial epithelial cells and in duct cells of the breast obtained by aspiration (see Chaps. 19 and 29). Zacharopoulos et al observed similar nuclear protrusions in occasional nonepithelial cells, suggesting that the phenomenon

P.200

is of a general nature and clearly worthy of further studies.

Ciliated Endocervical Cells

Endocervical cells showing recognizable **cilia, supported by a terminal plate**, are fairly frequent, particularly in brush specimens from the upper (proximal) segments of the endocervical canal. The nuclei of such cells are sometimes larger than average and somewhat hyperchromatic (Fig. 8-20D). The presence of the ciliated cells has been interpreted by some as evidence of **tubal metaplasia**, an entity that is discussed in Chapter 10.

Hollander and Gupta (1974) were the first to report the presence of **detached ciliary tufts** in cervicovaginal smears (Fig. 8-21A). This very rare event, occurring in about one-tenth of 1 percent of smears, cannot be correlated with time of cycle or age of patients. The ciliary tufts are fragments of ciliated endocervical cells, although sometimes their origin from the endometrium, or even the fallopian tubes, cannot be excluded. Next to detached ciliary tufts, remnants of the cell body with pyknotic nuclei may sometimes be observed (Fig. 8-21B). The phenomenon is similar to **ciliocytophthoria**, which was described by Papanicolaou in ciliated cells from the respiratory tract (see Chap. 19). So far, there is no evidence that the detached ciliary tufts in cervicovaginal smears are related to a viral infection, which may be the cause of ciliocytophthoria in the respiratory tract, and the mechanism of their formation is not clear.

The tiny **basal cells** of the endocervical epithelium have never been identified by us with certainty in normal smears although, undoubtedly, they should occur in energetic endocervical brush specimens.

Endocervical Cells and the Menstrual Cycle

The changes in the consistency of the cervical mucus during the menstrual cycle were mentioned above and will be discussed again below in the assessment of ovulation in Chapter 9. It was suggested by Affandi et al (1985) that the morphology of the endocervical cells follows

the events in the cell cycle. In the proliferative (preovulatory) phase, the cytoplasm of the endocervical cells in sheets is opaque and scanty and the nuclei are closely packed together. In the secretory (postovulatory) phase of the cycle, the cytoplasm is distended with clear mucus, the nuclei show degeneration (which, to this writer, appear to reflect the “nipple” formation described above), and, in cell sheets, are separated from each other by areas of clear cytoplasm. Affandi et al suggested that these differences in endocervical cell morphology in smears may be used to determine the occurrence of ovulation as reliably as endometrial biopsies. Affandi's observations have not been tested (see Chap. 9).

Cells of Normal Endometrium

The recognition and the presentation of endometrial cells vary according to the types of smears. By far, the best medium of analysis of the endometrial cells is the **vaginal smear**, which, unfortunately, has fallen out of fashion in recent years. The presence and the identification of endometrial cells in cervical smears, particularly those obtained by brush instruments, is less reliable and less frequent.

In cervical smears, the presence of endometrial cells during the childbearing age is closely related to the phases of the menstrual cycle. Such cells are common during the menstrual bleeding and for a few additional days as the endometrial cells are expelled from the uterine cavity. The upper limit of normal is the 12th day of the cycle. **The finding of endometrial cells in either vaginal or cervical smears, after the 12th day of the cycle, must be considered abnormal** (for further discussion of the clinical significance of this finding, see Chap. 13).

At the onset of the menstrual bleeding, sheets of small endometrial cells surrounded by blood and cell debris may be observed (Fig.8-22A). Easier to recognize are approximately **spherical or oval cell clusters** of variable sizes, wherein one can usually identify a **central core** made up of small, elongated, tightly packed **stromal cells** and, at the **periphery**, the much larger, vacuolated **glandular cells**. The latter are sometimes arranged in a rather orderly, concentric fashion around the core of stromal cells (Fig. 8-22B).

Endometrial stromal cells, not accompanied by glandular cells, are extremely difficult to identify during the first 3 or 4 days of the cycle. However, during the latter part of the menstrual flow, usually past the 5th or 6th day of the cycle, the endometrial stromal cells may be recognized as **small cells with phagocytic properties, resembling miniature macrophages**, often surrounding endometrial cells, singly and in clusters (Fig. 8-22C,D). On close inspection, the small cells, about 10 to 12 μm in diameter, are of irregular shape, their cytoplasm is delicate, either basophilic or eosinophilic, and the small nuclei are spherical or kidney-shaped and bland. Miniscule particles of phagocytized material may be found in the cytoplasm. These cells may be so numerous that Papanicolaou referred to them as the **exodus**. The close relationship between endometrial cells and the miniature macrophages suggested to Papanicolaou that the latter may be of endometrial stromal origin. Supporting evidence for phagocytic properties of endometrial stromal cells in tissue culture was provided by Papanicolaou and Maddi (1958, 1959).

Endometrial cells at **mid-cycle** appear as **clusters of endometrial glandular cells**, not accompanied by stromal cells (Fig. 8-23A,B). Such clusters are usually less compact and the peripheral cells are often loosely attached and may become completely detached. These clusters offer a good opportunity to study **individual glandular endometrial cells**, which vary in size from 10 to 20 μm , have a basophilic cytoplasm, are round or elongated, and often contain one or more **cytoplasmic vacuoles** of variable sizes. The nuclei in such cells are spherical, inconspicuous, opaque or faintly granular, measuring about 8 to 10 μm in diameter, and are sometimes provided with very small nucleoli. The size of the normal nuclei should be no larger than the size of the nuclei of intermediate or parabasal squamous cells, which are commonly present in smears. The cytoplasmic vacuoles may displace and compress the nucleus to the periphery of the cell. In poorly preserved, degenerated cells, the vacuoles may sometimes be distended and conspicuous. Occasionally, the **vacuoles may be infiltrated by polymorphonuclear leukocytes**. The differentiation of single endometrial cells from small macrophages is, at times, difficult, if not impossible. However, macrophages, as a rule, do not form clusters. The role of macrophages in the diagnosis of endometrial abnormalities is discussed in Chapter 13. **Endometrial stromal cells at mid-cycle** are very difficult to recognize because of their small size, unless found in the company of larger, endometrial glandular cells. Occasionally, the stromal cells show mitotic activity (Fig. 8-23C).

Endometrium in Smears of Women Wearing Intrauterine Contraceptive Devices

As has been stated above, the presence of endometrium in cervicovaginal smears, after the 12th day of the cycle, is

P.202

abnormal and must be a cause for concern. This matter is further discussed in Chapter 13 in reference to endometrial carcinoma. An important **exception to the rule** may be observed in wearers of intrauterine contraceptive devices (IUD), which may cause **endometrial shedding, predominantly at mid-cycle**. The clusters of endometrial glandular cells in smears are essentially similar in appearance to those shed during normal menstrual bleeding. Sometimes, however, the clusters are made up of cells with slightly atypical nuclei (Fig. 8-23D). The nuclei may be slightly hyperchromatic and granular but are generally of normal size. Knowledge of clinical history is essential in the correct interpretation of such findings. Other findings in IUD wearers are described in Chapter 13.

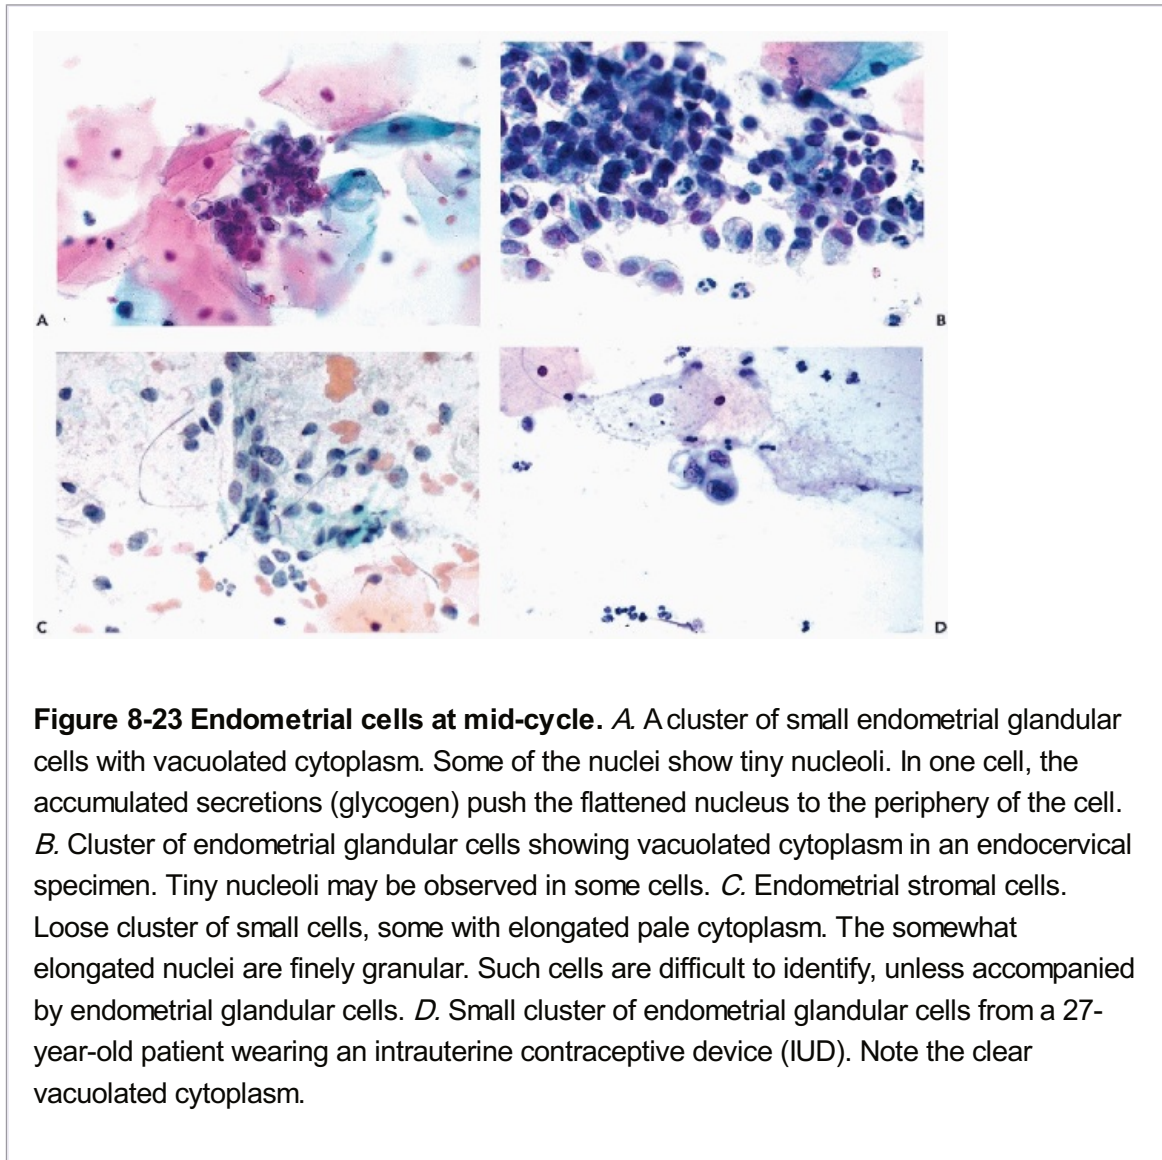

Figure 8-22 Endometrium in menstrual smears. *A.* Day 1 of bleeding: a cluster of endometrial cells in a background of blood, squamous cells, and debris. *B.* Day 6 of bleeding: typical spherical cluster of endometrial cells with the core formed by stromal cells and the periphery by poorly preserved large glandular cells. *C.* Exodus. Numerous small macrophages (modified stromal cells) surrounding a typical spherical cluster of endometrial cells. *D.* Exodus. Typical spread of small macrophages with vacuolated cytoplasm. Mitoses may occur, as shown in this photograph (*arrow*).

Endometrial Cells in Endocervical Brush Specimens

Vigorous brushing of the upper reaches of the endocervical canal may result in inadvertent sampling of the endometrium. As shown in Figure 8-24A, the recognition of endometrial cells under the scanning power of the microscope, may present significant difficulties. The endometrial cells may be **mistaken for cells of an endometrial adenocarcinoma**, particularly if they contain nucleoli (see Fig. 8-23B). The recognition is easier if entire tubular glands are present (Fig. 8-24B). The most significant problems occur when thick sheets of endometrial cells (Fig. 8-24C,D) are observed. Clusters of small stromal cells may be **mistaken for malignant cells** derived from a small-cell type of high-grade squamous neoplastic lesion (HGSIL), as discussed and illustrated in Chapter 11. The differentiation of the endometrial cells from endocervical cells is usually based on cell size with the endometrial cells being much smaller. Also, the endometrial cells show much less variability in nuclear sizes and lack intranuclear cytoplasmic inclusions, which are fairly frequent in endocervical cells (see Fig. 8-20B).

Determination of Phases of the Menstrual Cycle in Endometrial Samples

Endometrial smears obtained by direct sampling are a cumbersome and not always reliable means of determining the stage of the cycle, although the task may be somewhat easier with adequate brushing and liquid fixation, wherein differences between the phases of the cycle can be observed, as described above. Still, a combination of cervicovaginal smears and endometrial biopsies is simpler and more informative. The use of direct endometrial samples in the diagnosis of early endometrial carcinoma is discussed in Chapter 13.

CYCLIC CHANGES IN CERVICOVAGINAL SMEARS

Diagnostic cytology, as we know it today, was the outgrowth of an investigation of hormonal changes of the vaginal epithelium by Stockard and Papanicolaou (1917). As has been stated above, the vaginal squamous epithelium depends on estrogens for maturation and the microscopic examination of changes, occurring in squamous cells, is the principle of hormonal cytology, discussed in detail in Chapter 9. The vagina of rodents is the ideal target of such investigations. The squamous epithelium undergoes significant and readily defined light microscopic changes during the phases of the menstrual cycle, described by Papanicolaou in smears obtained by means of a small glass pipette. His studies of the **menstrual cycle in vaginal smears of women** led to the incidental discovery of cancer cells, as described in Chapter 1. The cyclic changes in the vaginal squamous epithelium of the menstruating woman are much less striking than in rodents. In fact, in many women, the estimation of the time of the cycle, based on the appearance of the squamous cells is, at best, only approximate. As described in Chapter 9, the most secure way to determine the cyclic changes is in a smear obtained by scraping the lateral wall of the vagina at some distance from the uterine cervix. Still, some information on the hormonal status of the woman can be obtained by studies of routine

cervical smears. The ideal sequence of cyclic changes, described below, is not too frequent. Numerous factors, including inflammatory changes, may account for deviations from the normal cycle.

As has been described above in reference to the cyclic changes in the endometrium, the first part of the menstrual cycle until ovulation (days 1 to 12 or 13), is governed by estrogens. Following ovulation, the events in the cycle are governed by progesterone (see Fig. 8-11). The effect of these hormones is reflected in squamous cells in cervicovaginal smears. The changes are described for a cycle of 28 days duration.

Days 1 to 6

The first day of menstrual bleeding is customarily considered the first day of the cycle. During the first 5 days of the cycle, the smears are characterized by the presence of **blood**, **desquamated endometrial cells**, singly and in clusters, and

P.204

polymorphonuclear leukocytes. The **squamous cells of intermediate type dominate.** **Such cells form clumps** and their **cytoplasm is folded** and degenerated. On the 4th or 5th day, the squamous cells begin to show less clumping and a better cytoplasmic preservation.

Figure 8-24 Endometrial cells in endocervical brush specimens. *A-C.* Typical presentation of endometrial cells at scanning magnification. In *A*, a cluster of glandular cells, also shown in Figure 8-23B. In *B*, typical endometrial tubular glands and stroma are easy to recognize. In *C*, a sheet of squashed endometrial glands. *D.* Higher-power view of the periphery of the cell cluster shown in *C*. The tiny endometrial stromal cells are much smaller and lack the cytoplasm of the endocervical cells (cfr. Fig. 8-19). These cells may be confused with neoplastic small cells from a high grade squamous intraepithelial neoplasia (see Chap. 12).

Days 6 to 13 or 14

During the 6th and 7th days, there is a gradual disappearance of blood. **Endometrial cells** in

well-preserved clusters, accompanied by large numbers of **small macrophages** (transformed stromal cells, **exodus**), may be observed up to the 10th or even 12th day (see Fig. 8-22C). From the 6th or 7th day on, the squamous cells are predominantly of the **basophilic intermediate variety with vesicular nuclei**. Gradually, the basophilic cells are **replaced by mature, flat eosinophilic superficial cells**, characterized by small pyknotic nuclei and transparent flat eosinophilic cytoplasm (see Fig. 8-15A,B). These cells predominate in vaginal smears at the time of ovulation, between the 12th and the 14th day. At this time, small **nipple-like nuclear protrusions may occasionally be seen in the endocervical cells** (see Fig. 8-20C). The **thick cervical mucus forms fern-like crystalline structures** that vanish just prior to ovulation, when the mucus becomes liquid.

Days 14 to 28

Following ovulation, cytoplasmic folding may be noted in the superficial squamous cells. **The proportion of intermediate squamous cells gradually increases**, indicative of a reduced level of maturation of the squamous epithelium under the impact of progesterone. As the time of menstrual bleeding approaches, the intermediate cells **form clusters or clumps**. With the approach of menstrual bleeding, there is a marked increase in lactobacilli, resulting in **cytolysis** of the intermediate cells. The cytolysis results in “moth-eaten” cell cytoplasm, nuclei stripped of cytoplasm (**naked nuclei**) in a smear with a background of cytoplasmic debris (**“dirty” type of smear**) (see Chap. 10). This appearance of the smear persists until the new cycle begins with the onset of the menstrual bleeding.

Cyclic Changes in Direct Endometrial Samples

Additional information pertaining to the status of the endometrium may be obtained by means of direct endometrial

P.205

sampling by various methods (see Chap. 13). Some of the newer methods of endometrial sampling, such as collection of the material obtained by direct brushings in liquid media and processing of the material in the form of cytospins, have been described by Maksem and Knesel (1995). In ideal material, stages of cell cycle may be recognized.

Figure 8-25 Direct endometrial smears in late proliferative (A) and secretory (B) phases of menstrual cycle. Both smears show glandular cells that are densely packed. Mitotic activity is evident in the proliferative phase (A); cells have more abundant cytoplasm in the secretory phase (B).

In the **proliferative phase**, the **cuboidal glandular cells form honeycomb clusters**, characterized by spherical nuclei, varying somewhat in size. Small nucleoli and occasional **mitotic figures** may be observed (Fig. 8-25A). In good preparations, whole tubular glands and stroma may be observed. The **stroma** is composed of small spindly cells. During the **secretory phase**, the **glandular cells** are somewhat larger because of more abundant vacuolated cytoplasm (Fig. 8-25B). In good preparations, whole convoluted glands and somewhat **larger stromal cells** may be observed. The differentiation of the nuclei of the glandular cells from those of stromal cells is rarely possible. In fact, all the nuclei appear so similar that they very strongly suggest a common origin of both types of cells.

Determination of ovulation should never be attempted on direct endometrial samples. The method causes significant discomfort to the patient, it is costly, and not particularly accurate.

THE MENOPAUSE

The menopause is caused by the **cessation of cyclic ovarian function**, resulting in the arrest of menstrual bleeding. The onset of the menopause is rarely sudden, the changes are usually gradual and may stretch over a period of several years, with gradual reduction in duration and frequency of the menstrual flow. The age at which complete menopause occurs varies. As a part of a project on detection of occult, asymptomatic endometrial carcinoma (Koss et al, 1984), information was obtained on the age of onset of the menopause in 2063 women (Table 8-1). It may be noted that it is quite normal for 50% of the American women to continue menstruating up to the age of 55 and even beyond. The significance of delayed menopause as a possible risk factor for endometrial carcinoma is discussed in Chapter 13.

Clinical and cytologic menopause do not necessarily coincide. Occasionally, a patient who is still menstruating regularly presents the cytologic image of early menopause. Conversely, at least 30% of the women who have entered their clinical menopause, may display a smear pattern reflecting varying degrees of ongoing hormonal activity and may even reveal some cyclic changes.

The most important manifestations of the menopause are associated with **reduced production of estrogen**, although other complex changes in the endocrine balance are known to occur. The **ovaries**, the principal source of estrogen, become scarred and hyalinized without any remaining evidence of ovogenic activity. Because of estrogen deficiency, there is a cessation of endometrial proliferation with resulting **endometrial atrophy**. The endometrium becomes very

P.206

thin. Scanty endometrial glands, some of which are enlarged and cystic, are seen within a depleted stroma (Fig. 8-26A).

TABLE 8-1 ONSET OF MENOPAUSE IN A COHORT OF 2,063 NORMAL WOMEN *		
Age in Years at Onset of Menopause	Number in Group	% of Cohort
<39	43	2.0
40-44	138	6.7

45-49	789	38.2
50-55	1,031	50.0
≥55	62	3.0
Total 2,063		99.9 (rounded to nearest decimal point)

*From Koss et al. Obst Gynec 64:1-11, 1984.

Figure 8-26 Postmenopausal atrophy of endometrium (A) and of squamous epithelium (B). A. Dispersed small glands in fibrotic stroma. B. The number of cell layers is reduced and there is lack of surface maturation.

Gradual estrogen depletion will also result in **gradual arrest of maturation of squamous epithelium**, with gradual loss of the superficial cell layers. In the final stages of atrophy, the surface of the squamous epithelium is composed of parabasal cells (Fig. 8-26B). The **endocervical epithelium** also shows evidence of atrophy; the columnar endocervical cells are often more cuboidal in shape, and their cytoplasm becomes opaque. A complicating factor in the evaluation of the menopausal cytology is the **cessation of the secretory activity of the endometrial and endocervical cells**, with resulting **dryness** of the lower genital passages, primarily the vagina. In smears, dryness **causes a number of artifacts**, similar to air drying of the smear, described below. In the absence of protective layers of the superficial squamous cells and because of dryness, the epithelium of the lower genital tract offers little resistance to bacterial invasion, resulting in vaginitis and cervicitis. In the presence of inflammation, the surface of the squamous epithelium becomes ragged and parabasal cells may be observed desquamating directly from the loose surface. The resulting **inflammatory changes** still further obscure the cytologic pattern, resulting in cell images that may mimic cancer. Indeed, recognition of cancer cells in atrophic postmenopausal smears may occasionally present substantial difficulties.

TABLE 8-2 VAGINAL SMEAR PATTERNS IN MENOPAUSE BASED ON EXAMINATION OF 1,100 CASES

Duration of Menopause	Estrogenic (Early Menopausal Pattern)	Intermediate ("Crowded" Pattern)	Atrophic
2-10 years			
599 cases	21%	55%	24%
10 years or more			
512 cases	14%	49%	37%

Stoll P. Vaginal smears in the menopause. Acta Cytol 4:148-150, 1960.

Basic Cytologic Patterns

Three basic cytologic patterns of the menopause may be differentiated—**early menopause**, **"crowded" menopause**, and **advanced or atrophic menopause**. The distribution of the patterns is shown in Table 8-2. A sharp separation of the three postmenopausal smear patterns is not always possible in practice, since one pattern may merge into another.

Early Menopause: Slight Deficiency of Estrogens

The smears are essentially those of the childbearing age, except for a **reduction in the proportion of superficial squamous cells**. The smears are composed predominantly of dispersed intermediate cells, occasionally showing cytolysis, and some large parabasal cells. These cells contain vesicular nuclei of normal size, about 8 μ m in diameter. Because of a generally smaller size of the squamous cells, however, it may appear to a casual observer that the nuclei are diffusely enlarged. This

P.207

smear pattern may be associated with diminishing, increasingly scanty menstrual flow or with cessation of menses. In many women, this smear pattern may persist for many years after the menopause and, perhaps, for life. It has been my impression that the smear patterns suggestive of persisting estrogen activity correlate positively with sexual activity of postmenopausal women. Women who lead an active sexual life after the menopause appear to be less likely to develop postmenopausal atrophy than sexually inactive women. This anecdotal observation has received ample support from a study by Leiblum et al (1983).

Figure 8-27 Cytologic patterns of menopause. *A.* “Crowded” menopause. The smear is composed of large parabasal cells forming clusters. *B.* Navicular cells in crowded menopause. Note the boat-shaped cells containing yellow deposits of glycogen that may push the nuclei to the periphery. *C.* Atrophic smear pattern—nuclear enlargement type. The smear is composed of parabasal cells with seemingly enlarged pale nuclei. However, the nucleocytoplasmic ratio is not altered. There are scattered inflammatory cells in the background. *D.* Atrophic smear pattern, eosinophilic-pyknotic type. The smear is composed of small parabasal cells with eosinophilic cytoplasm. Nuclear break-up is evident in several cells. Note filaments of DNA in the background.

“Crowded” Menopause: Moderate Deficiency of Estrogens

This type of smear usually follows the smear of early menopause and is characterized by **thick, crowded clusters of intermediate and large parabasal cells** (hence, the name of this type of smear, proposed by Papanicolaou). The cells are well preserved and there is little, if any, dryness. Because of small size of the cells, their nuclei may appear to be relatively large but are of normal sizes (Fig. 8-27A). The cytoplasm frequently contains deposits of glycogen in the form of yellow deposits, similar to **navicular cells** observed in pregnancy (Fig. 8-27B).*

Atrophic or Advanced Menopause

The pattern of atrophic menopause appears to be invariably preceded by early or crowded menopause or both. There is always a stage of transition between the normal cycle and the advanced menopause, even if the latter was brought about by oophorectomy. The atrophic menopause represents a final stage of involution of the female genital tract.

P.208

The **cytologic patterns** of the advanced atrophic menopause are influenced by **dryness of the genital tract and scarcity of recoverable cellular material**, resulting in preparations that contain relatively few cells. The dominant squamous cells are of the **parabasal type**, although it is not uncommon to see a few scattered, more mature cells, evidently corresponding to nonatrophic areas of the squamous epithelium. Two **main effects of dryness** may be

observed. One is the **uniform enlargement of the parabasal cells**, accompanied by a characteristic uniform gray discoloration of the **enlarged opaque nuclei** (the **nuclear enlargement type**; Fig. 8-27C). The second pattern is marked **eosinophilia of the cytoplasm** accompanied by **nuclear pyknosis and break-up of nuclei or karyorrhexis** (the **eosinophilic-pyknotic type**; Fig. 8-27D). The two patterns may appear simultaneously. As a result of nuclear break-up, **basophilic filaments of DNA** are often seen in the background. In the smears of the eosinophilic pyknotic type, there may be a **striking variation in size and shape of squamous cells**. Sometimes perfectly normal superficial squamous cells may occur in such smears, next to small parabasal type cells (Fig. 8-28A). **Sheets of spindly squamous cells**, with elongated cytoplasm and relatively large and dark-staining nuclei, may make their appearance in atrophic smears, most likely an artifact of smear preparation (Fig. 8-28B). Such cell sheets may be mistaken for spindly cells of squamous carcinoma, even though their nuclei are not enlarged or otherwise abnormal (see Chap. 11).

Figure 8-28 Cytologic patterns of menopause. *A.* Atrophic smear pattern with scattered mature superficial squamous cells. *B.* Spindly pattern of squamous cells—an artifact caused by dryness. Note normal nuclei. *C.* A foreign body giant cell in a postmenopausal atrophic smear. Note phagocytized cell debris in the cytoplasm. *D.* Blue or purple amorphous bodies, either inspissated mucus or degenerated parabasal cells, in postmenopausal atrophy.

The **endocervical cells in cervical smears, even if obtained by brushes, are usually scarce or absent**. When present, the **endocervical cells are smaller than during the childbearing age**, although their columnar or cuboidal configuration is still preserved. The nuclei, although of normal size, may appear somewhat hyperchromatic and the cytoplasm is scanty, opaque, and shows no evidence of secretory activity, except for an occasional vacuole.

As a consequence of extensive cell necrosis, **mono- or multinucleated macrophages**, often containing fragments of phagocytized material, are commonly observed in atrophic smears (Fig. 8-28C). **Multinucleated macrophages may also be found in normal endometrial samples** of postmenopausal women. These cells usually accompany scanty fragments of endometrial

glands and sparse stromal cells, corresponding to atrophic endometrium of the menopause.

Round or oval **globules of inspissated blue-staining material, probably mucus**, about the size of parabasal squamous

P.209

cells, may appear in the late menopausal smears (Fig. 8-28D). Occasionally, the center of the globule is denser than the periphery and the structure may resemble a cell with a markedly hyperchromatic nucleus, **mimicking a cancer cell**. On close examination, the lack of actual structure within the globule is obvious and its true nature will be recognized. Such globules may, on rare occasion, be quite numerous in a vaginal smear and may result in an erroneous diagnosis of cancer. Some observers believe that the **blue globules** are not made up of inspissated mucus, but represent **degenerated small parabasal cells** (Ziabkowski and Naylor, 1976). This latter view is not sustained by convincing evidence. In any event, it is generally agreed that these structures are of no significance, except as a potential source of diagnostic error.

Because of loss of the protective superficial layers of squamous epithelium, **inflammatory processes** are commonly seen in smears of this type. **In the presence of vaginitis or cervicitis**, the background of the smear may contain **numerous leukocytes and cell debris** (see Fig. 8-27C). The inflammatory patterns will be described in detail in Chapter 10.

In some atrophic smears, **nuclear pyknosis** may be quite striking and may **mimic the hyperchromasia of cancer cells**. As is discussed in Chapter 11, the nuclei of cancer cells in postmenopausal women are usually very large, irregular and often markedly hyperchromatic, whereas the pyknotic nuclei of advanced menopause are usually enlarged only in proportion to the size of the cell, with retention of the normal nucleocytoplasmic ratio. Still, in some cases, to document the presence of cancer cells may require **administration of estrogen** that will normalize the atrophic cell population and enhance the abnormal appearance of cancer cells.

It has been the experience in this laboratory that the pronounced degenerative phenomena associated with atrophic menopause, resulting in cellular abnormalities, are usually observed in women whose vaginas have been free of outside contacts for prolonged periods of time. If the sampling is repeated within a few days, there is usually a striking improvement and sometimes there is a complete disappearance of abnormalities.

Figure 8-29 Cytology of prepubertal females. *A.* Newborn female. Urine sediment contains mature squamous cells, presumably of vaginal origin. *B.* Vaginal smear from a 7-year-old girl with vaginal discharge. The epithelial squamous cells are of small parabasal type—resembling a postmenopausal smear. Marked inflammatory exudate is present in the

background.

CYTOLOGY OF PREPUBERTAL FEMALES

Much of our knowledge of the cytologic patterns of vaginal smears in infants and children is derived from work by Fraenkel and Papanicolaou (1938) and Sonek (1967, 1969). The optimal method of study is a **vaginal smear** obtained by means of a very small pipette. **Urinary sediment** may sometimes be successfully used for the study of hormonal levels in a very small child (see urocytogram, discussed in Chap. 9).

In **newborn infants**, the squamous epithelium of the cervix and the vagina usually assumes the appearance of maturity under the influence of maternal hormones. The vaginal smears, or urinary sediments, in newborn infants are composed of superficial squamous cells comparable with those of women in the childbearing age (Fig. 8-29A). Within a few days after birth, the percentage of superficial cells drops in favor of small intermediate cells. This smear make-up changes within 2 weeks after birth by an increase in parabasal cells. After the 4th week of life, the smears are composed chiefly of parabasal cells (Fig. 8-29B). This smear type remains essentially unchanged until the approach of puberty, when there is a gradual maturation of the squamous epithelium of the genital tract. In the presence of an inflammatory process, the smear background may show leukocytes.

There are several **reasons for studying cell preparations from the prepubertal girl**.

The low squamous epithelium of the child, not unlike that of a postmenopausal woman, is susceptible to **infections**. A vaginal smear may be of assistance in the identification of the causative agent, such as *Trichomonas vaginalis*. Occasionally, it may be of interest to study the extent and the duration of the epithelial **response to hormonal medication** by vaginal smears. If the presence of an **ovarian tumor with endocrine activity** is suspected, the study of vaginal cytology is sometimes helpful in establishing the diagnosis. For instance, in the presence of feminizing tumors,

P.210

such as some of the granulosa cell tumors of the ovary, there may be maturation of squamous epithelium with a corresponding change in the smear pattern (see Chap. 15). A vaginal smear may also be helpful in the evaluation of various **endocrine disorders** (see Chap. 9).

PREGNANCY AND ABORTION

Pregnancy

Pregnancy constitutes a major physiologic upheaval in the life of a woman. The sequence of events in pregnancy is beyond the scope of this book and the readers are referred to other sources for a comprehensive review of this complex subject. This brief summary will stress those morphologic changes that may have an impact on cytology of the female genital tract.

Formation of Placenta

A detailed account of the formation of the human placenta may be found in the book by Boyd and Hamilton (1970). Through proliferation of the external cells of the embryonal *anlage*, a placenta is formed within a few days following implantation. The placental villi are initially lined by **trophoblastic cells**; the outer layer of large, multinucleated syncytial cells (**syncytiotrophoblasts**) and the inner layers of mononucleated **cytotrophoblasts** (also known

as Langerhans' cells). By the 28th week of pregnancy, the cytotrophoblasts are reduced in number and the syncytial outer layer is the dominant lining of the villi. The placenta produces human **chorionic gonadotropin (hCG)** that can be used as a marker of cells derived from the placenta.

Formation of Decidua

The fertilization of the ovum takes place in the fallopian tube, whence the products of conception travel to the endometrial cavity, where the implantation takes place. At the site of the implantation, the cells of the endometrial stroma are transformed into **decidual cells**, which are **large, eosinophilic, polygonal cells, with round, vesicular nuclei**. The decidua, especially at the site of implantation of the ovum (decidua vera), carries the maternal vasculature, providing the fetus with necessary nutrients. Foci of **decidua may occur within the cervix**, where they may be confused with cancer in biopsy material (Fig. 8-30).

The Effects of Pregnancy on the Epithelia of the Cervix and Vagina

In histologic material, the cytoplasm of the **squamous epithelial cells** becomes markedly distended with glycogen, giving the cells a vacuolated appearance. The surface of the epithelium is often formed by intermediate squamous cells. There is usually some enlargement in the size of the **endocervical epithelial cells**. The endocervical glands are structurally more complex as a result of the elongation of the individual branches and are often filled with mucoid material (see Fig. 8-30). An eversion of the endocervix with the presence of a rim of endocervical tissue around the external os is frequent.

Figure 8-30 Decidual changes in the uterine cervix. The sheet of large, decidual cells in the cervical stroma may be mistaken for cancer. The endocervical glands are distended and filled with secretions.

Cytologic Manifestations of Pregnancy

Squamous Cells

The effects of pregnancy on the squamous epithelium are frequently, but not always, reflected in vaginal smears after the 2nd month. These changes are characterized by **clustering of intermediate squamous cells** and the predominance of **navicular cells**, the latter defined by yellow **cytoplasmic deposits of glycogen**, displacing the nuclei to the periphery, and sharply defined, accentuated borders (Fig. 8-31A). In the later stages of pregnancy, extensive **cytolysis** of squamous cell cytoplasm by lactobacilli is not uncommon (Fig. 8-31B).

Von Haam (1961) estimated that only 60% to 77% of pregnant women show the pattern of navicular cells. Furthermore, it has been pointed out above that early menopause may result in a smear pattern closely resembling pregnancy. Thus, the **presence of navicular cells is not diagnostic of pregnancy**, but the condition may be suspected when numerous such cells are present in smears from young women of childbearing age with a history of amenorrhea. The final diagnosis of pregnancy must be rendered by means other than a cytologic preparation.

Endocervical Cells

Endocervical cells may appear in somewhat increased numbers in cervical smears and may be larger than normal; the cytoplasm is often mucoid, and the nuclei are prominent, granular, and may show small nucleoli.

Uncommon Pregnancy-Related Findings

Trophoblastic Cells

Syncytiotrophoblasts are very rarely found in smears in normal pregnancy and are somewhat more frequent in smears preceding a spontaneous abortion. The cells are large, irregular, basophilic or eosinophilic, and contain a **variable number of large, often hyperchromatic homogeneous nuclei of uneven sizes** with a finely granular nuclear texture (Fig. 8-31C,D). Nearly identical cells may

P.211

be observed in **choriocarcinoma**, a malignant tumor derived from placental trophoblasts (see Chap. 18). Somewhat **similar multinucleated cells** may be seen in **herpes simplex infection** (see Chap. 10). It is questionable whether or not the mononucleated **cytotrophoblasts** may ever be correctly recognized in smears based on their morphology. Fiorella et al (1993) used a cocktail of **antibodies to human chorionic gonadotropin (hCG) and human placental lactogen** to identify syncytiotrophoblasts and cytotrophoblasts in smears during pregnancy. They could identify trophoblastic cells in 6 of 39 women and failed to observe any relationship of the presence of these cells with spontaneous abortion. It may be concluded from this study that cytotrophoblasts may sometimes occur in normal pregnancy but cannot be recognized without immunostaining. Frank and Bhat (1991) pointed out that **residual trophoblastic tissue may persist for several months after delivery and may be the source of abnormal cells** that may be confused with cancer.

Figure 8-31 Cytologic manifestations of pregnancy. *A.* Navicular squamous cells, 2nd month of pregnancy. Note the deposits of yellow material, pushing the nuclei to the side of the cell. *B.* Cytolysis. The squamous cells are reduced to nuclei surrounded by wisps of cytoplasm. The change is caused by lactobacilli. *C,D.* Cytotrophoblasts. Abortion in a 29-year-old woman. The striking large cells contain multiple homogeneous nuclei of variable sizes (compare with cells of choriocarcinoma in Chap. 18).

Decidual Cells

Decidual cells may be identified in cervical smears on those rare occasions when decidual changes occur in the uterine cervix. These are **large mononucleated cells**, occurring singly or in clusters, with abundant eosinophilic or basophilic, faintly vacuolated cytoplasm and prominent, centrally located **vesicular nuclei containing identifiable nucleoli** (Fig. 8-32). Occasionally, the **nuclei of the decidual cells may be dense and hyperchromatic**, particularly when derived from degenerating decidual tissue (Fig. 8-33). The decidual cells may be confused with cancer cells, as noted by Danos and Holmquist (1967), Schneider and Barnes (1981), and Pisharodi and Jovanoska (1995). Their recognition may be difficult in the absence of clinical history of pregnancy or amenorrhea and may require a biopsy for accurate diagnosis.

Arias-Stella Phenomenon

The abnormality, first described by Arias-Stella in 1954, is characterized by **large cells with large, hyperchromatic nuclei** located within the **endometrial gland lining in the presence of products of conception or in ectopic pregnancy**. Silverberg (1972) and Reyniak et al (1975) recorded the presence of Arias-Stella changes in endometrial glands, following curettage for interruption of pregnancy. The protruding large cells stand out among the normal endometrial cells (Fig. 8-34A). The great variability of the nuclear morphology was emphasized by Arias-Stella. Wagner and Richart (1968) reported that the Arias-Stella cells are polyploid (i.e., they contain a multiple of the normal amount of DNA). The mechanism

P.212

of their formation is unclear. Similar abnormalities may be observed in histologic sections of the **endocervical epithelium** (Schneider, 1981) (Fig. 8-34B), **where they may be confused**

with an adenocarcinoma (Cove, 1979). Schneider observed the endocervical Arias-Stella reaction in 9% of hysterectomy specimens obtained during pregnancy. **Similar changes may be observed in the endocervical epithelium in women receiving contraceptive hormones** with high progesterone content (see Chap. 18). The significance of such cell changes as a potential diagnostic pitfall in cytology was emphasized, notably by Albukerk (1974) and by Shrager (1977) and by Benoit and Kini (1996). The exact identification of the highly abnormal and rare Arias-Stella cells in cytologic material is still a matter for some debate. Through the courtesy of Dr. Albukerk, I was privileged to examine some of his material. Arias-Stella cells appear in smears as **large cells with a single, large, somewhat hyperchromatic nucleus** and a finely vacuolated cytoplasm (Fig. 8-34C). In another case of a 29-year-old pregnant woman, we observed cells with large nuclei that were no longer present in postpartum smears (Fig. 8-34D). It was assumed that these were Arias-Stella cells. The cases recorded so far appear to be mainly related to ectopic pregnancy in which the products of conception do not prevent the shedding of such cells. Thus, the clinical history appears to be of critical diagnostic value in the assessment of such cells that otherwise may be readily mistaken for cancer cells.

Figure 8-32 Decidual reaction, cervical smear, 41-year-old pregnant woman. A,B. Large cells of variable shapes with prominent nuclei containing conspicuous single or multiple nucleoli. **C.** Biopsy of a cervical polyp with decidual change in the stroma. (Case courtesy of Dr. N.W. Cunningham.)

Cytologic Assessment of Pregnancy at Term

During the 1950s, there was considerable interest in the application of the cytologic techniques in obstetrics, particularly with regard to the determination of pregnancy at term. With contemporary obstetrical techniques of fetal monitoring, the clinical value of these observations has diminished considerably. A brief account of the principal observations is appended for historical reasons.

In 1955, Lemberg-Siegfried and associates, and, in 1958 Lichtfus et al reported that pregnancy at term is characterized by the following cytologic changes:

- Rapid reduction in the number of clusters of intermediate squamous cells
- Increase in single superficial squamous cells with eosinophilic cytoplasm (increase in the eosinophilic index) or pyknotic nucleus (increase in the karyopyknotic index; for definitions of indices, see Chap. 9). Lichtfus et al cautioned that this evaluation is valid only if the smear has been obtained from the lateral wall of the vagina in the absence of infection and before the rupture of fetal membranes

Initially, these observations received wide support, particularly among European observers, but were subsequently seriously challenged. Abrams and Abrams (1962), Hindman et al (1962), Ruiz (1965), and Jing et al (1967) failed to observe the rapid transition of the prior-to-term pattern to the at-term pattern previously reported. In a very thorough study of serial smears obtained at weekly intervals from 135 antepartum patients, Abrams and Abrams failed to observe the at-term pattern in 66% of patients. In the remaining 34% of patients, the at-term pattern was observed but could not be correlated with the onset of labor. Since these authors meticulously followed the criteria of Lichtfus et al, it is clear that **the value of cytologic techniques in defining pregnancy at term is debatable.**

Rupture of Fetal Membranes

Rupture of fetal membranes results in spilling of **amniotic fluid** into the vagina. This fluid contains numerous **anucleated squamous cells** desquamated from the skin of the fetus (so-called vernix caseosa). Such cells may be found in the

P.213

vaginal smear if it is obtained at the proper time. For further discussion of the cytology of amniotic fluid, see Chapter 26.

Figure 8-33 Degenerating decidua in cervical smears. *A.* Cells with hyperchromatic nuclei containing small nucleoli. *B.* Corresponding cervix biopsy showing degenerating decidua.

The Postpartum Period

During the postpartum period, there is often no evidence of estrogen activity and many women display an **atrophic smear pattern** with predominance of parabasal squamous cells. The views differ on the exact proportion of women with this smear pattern and the differences may be due to the techniques used. Butler and Taylor (1973), using a scrape smear of the lateral wall of the vagina, observed the atrophic pattern in only 28% of their population of postpartum women. McLennan and McLennan (1975), using a

P.214

mixed cervicovaginal smear 3 to 6 weeks postpartum, observed the atrophic pattern in 32% of nonlactating and 72% of lactating women. It must be noted that, **during lactation**, intermediate and large parabasal **cells of navicular type**, with large cytoplasmic glycogen deposits, may be observed (Fig. 8-35).

Figure 8-34 Arias-Stella reaction in pregnancy. Arias-Stella reaction in the endometrium (*A*) and the endocervix (*B*). Note scattered large cells with hyperchromatic nuclei in

endometrial and endocervical glands. *C.* Isolated large cells in a cervical smear in a case of abortion presumed to be Arias-Stella cells. *D.* Several large cells in the smear of a 29-year-old, 7-month pregnant woman, presumed to be Arias-Stella cells. (*C:* Courtesy of Dr. Albukerk.).

Figure 8-35 Postpartum smear, composed of navicular cells. (P stain; $\times 160$.)

The return to normal cyclic patterns varies from patient to patient. In the great majority of patients, whether lactating or not, the cyclic pattern will be evident 6 months after delivery. Persistence of atrophic smear pattern, beyond 1 year after delivery, may indicate a serious endocrine disorder (see Chap. 9).

Alleged Pregnancy-Related Neoplastic Abnormalities

In the 1960s and 1970s, several articles, discussed in Chapter 11, attributed significant, cancer-like abnormalities of squamous and endocervical cells to pregnancy. The only cytologic changes characteristic of pregnancy are those described above. **Other disorders, particularly cytologic abnormalities consistent with precancerous lesions or cancer, are incidental to pregnancy** as recently reemphasized by Pisharodi and Jovanoska (1995) and by Michael and Esfahani (1997). To be sure, some of the cytologic findings, such as the presence of decidual cells, syncytiotrophoblasts, or Arias-Stella cells in smears, may be difficult to interpret and must be differentiated from manifestations of cancer, described in subsequent chapters of this book.

Cytology of Spontaneous Abortion

Although abortion is not, strictly speaking, a manifestation of normal events in the life of a woman, it appears appropriate to discuss it in conjunction with the events of normal pregnancy rather than elsewhere in this book. There are no cells diagnostic of abortion. A smear obtained during abortion may contain **navicular cells**, fresh blood, and inflammatory exudate.

Syncytiotrophoblastic cells may be noted (see Fig. 8-31 C,D). On the rarest occasions, **elongated, smooth muscle cells** in smears (Fig. 8-36) will testify to trauma to the uterine wall. However, smooth muscle cells may also be derived from ulcerated submucous leiomyomas (fibroids), another very rare event (see Chap. 10).

Figure 8-36 Smooth muscle cells in a cervical smear after abortion. Elongated cells with tapered cytoplasm and small central nuclei. (Oil immersion.)

Threatened Versus Inevitable Abortion

It is debatable whether cytologic techniques are of clinical value in distinguishing a threatened abortion from an inevitable abortion. Still, if an early pregnancy is associated with bleeding, it is occasionally possible to predict, in vaginal smears, whether or not an abortion is inevitable. A **preponderance of superficial squamous cells with pyknotic nuclei**, rather than the characteristic pattern of pregnancy consisting of intermediate and navicular cells, will usually indicate excessive estrogenic activity and may suggest the inevitability of an abortion. A study of the cells of the urinary sediment may be substituted for a vaginal smear. The information obtained from cytologic studies is of only relative value and should be used in conjunction with a careful clinical evaluation. Genetic studies on **fetal tissue from spontaneous abortions** (Carr, 1963; Szulman, 1965) demonstrated that, in many cases, the fetus carries **significant chromosomal abnormalities**, suggestive of major genetic defects. It appears probable that, in some cases at least, a spontaneous abortion is a natural defense against the birth of an abnormal child. The situation is different in habitual aborters, in whom a hormonal imbalance may exist.

THE NORMAL VAGINAL FLORA

The normal flora of the vagina varies from person to person, but ***Lactobacillus* (bacillus Döderlein)** is usually the preponderant organism. This organism is a **gram-positive slender rod** staining a pale blue by the Papanicolaou method. The bacterial rods may either be observed in the background of the smear (Fig. 8-37A) or may accumulate on the surface of

squamous cells (Fig. 8-37B). The organism utilizes the **glycogen** contained in the cytoplasm of the intermediate and parabasal squamous cells and causes their

P.215

disintegration or cytolysis (see Fig. 8-31B). Fully mature superficial squamous cells are less likely to be cytolized, perhaps because of the presence of a firm cytoplasmic skeleton.

Lactobacillus survives best at a vaginal pH of 5, which is maintained by glycolysis. For further discussion of lactobacilli, see Chapter 10.

Figure 8-37 Lactobacilli (*b. vaginalis* or Döderlein bacilli) in cervicovaginal smears.

A,B. Grampositive rods of various length may occur in the background of the smears or on the surface of the squamous cells. See Figure 8-31B.

CELLS OTHER THAN EPITHELIAL IN NORMAL SMEARS

Leukocytes

A variety of leukocytes may be observed in smears, even in the absence of inflammatory processes. Lymphocytes and polymorphonuclear leukocytes are frequently seen trapped in the cervical mucus. Plasma cells, which are very uncommon in smears, usually signify chronic inflammatory processes (see Chap. 10).

Macrophages (Histiocytes)

Small mononuclear macrophages are often seen during the late part of the menstrual bleeding (**exodus**, see above). The larger **mononucleated macrophages** are medium-sized cells (about 25 to 30 μm in diameter) with basophilic, often faintly vacuolated, cytoplasm that may contain fragments of phagocytized material. The nuclei are spherical or kidney-shaped with a finely granular chromatin and occasionally tiny nucleoli (Fig. 8-38A). Such cells are fairly common in cervical smears and may mimic endometrial or endocervical cells. The presentation and significance of such cells in vaginal smears in the diagnosis of endometrial cancer is discussed in Chapter 13. **Multinucleated macrophages** that may occur in smears are usually associated with the menopause, foreign bodies, or chronic inflammatory processes and are described above (see Fig. 8-28C) and discussed further in Chapter 10.

Figure 8-38 A. Sheets of macrophages with vacuolated cytoplasm. Note the relatively large nuclei of variable sizes. B. Spermatozoa in a cervicovaginal smear.

Spermatozoa and Cells of Seminal Vesicles

Spermatozoa are frequently observed in material from the female genital tract. Meisels and Ayotte (1976) recorded the presence of spermatozoa in nearly 10% of all smears of women between the ages of 25 and 40 and, with lesser frequency, in adult women of other age groups.

Well-preserved **spermatozoa** with the characteristic

P.216

dense heads and thin, elongated flagella (tails) are readily identified (Fig. 8-38B). The head may be somewhat variable in size and configuration; it is most commonly egg-shaped and, in Papanicolaou stain, shows an uneven distribution of chromatin. The pole of the head attached to the flagellum usually appears somewhat denser than the opposite pole. This is very likely an artifact of fixation or preparation because, in material optimally fixed for light microscopy, the chromatin distribution is uniform throughout the head. The basic ultrastructure of the flagellum is similar to that of a cilium, described in Chapter 2. The energy required for the movement of the spermatozoon is provided by numerous mitochondria located along the flagellum. Degenerated spermatozoa or spermatozoa killed by spermicidal agents are also commonly observed in cytologic preparations from the female genital tract. The flagella are usually partially or completely destroyed and the heads are enlarged, but not uniformly so. In clusters, the degenerated spermatozoa appear as a collection of oval shaped nuclei of variable sizes with remnants of flagella attached to them.

Spermatozoa may be also phagocytized by macrophages. In such instances, the heads of spermatozoa may be observed within the cytoplasm of the macrophage, whereas the tails may be outside the cell (see Chap. 33; Fig. 33-6C).

Cells originating in **seminal vesicles** may also be observed in vaginal smears. Such cells, noted in about 10% of patients with spermatozoa, may have conspicuously **large, hyperchromatic nuclei** and are identifiable by the presence of **cytoplasmic granules of brown lipochrome pigment** (see Chap. 33). Spermatozoa and other cells of male origin may be identified in cervicovaginal material by fluorescent in situ hybridization (FISH) technique with probes to chromosomes X and Y (Roa et al, 1995). Such cells were detected in some women 3 weeks after coitus. These observations are of value in medicolegal cases (Collins et al, 1994).

ACELLULAR MATERIAL AND FOREIGN BODIES IN CERVICOVAGINAL SMEARS

Curschmann's Spirals

Coiled spirals of inspissated mucus with a dense core and translucent periphery, identical in appearance to Curschmann's spirals seen in sputum (see Chap. 19), may occasionally be observed in cervical or vaginal smears. Prolla (1974) reported finding such structures in six of 5,635 consecutive vaginal and cervical smears and pointed out that all six women were heavy cigarette smokers. He suggested that the vaginalcervical Curschmann's spirals reflect a systemic effect of cigarette smoking. In an extensive study of this phenomenon, Novak et al (1984) observed Curschmann's spirals with a prevalence of 1 in 1,700 cervicovaginal smears and failed to note any relationship with smoking or extrinsic factors. Yet, in some cases at least, the possibility of extraneous origin of the spirals found in the vaginal pool must be considered. In one such case, a possible source was the sputum of an asthmatic sexual partner (Fig. 8-39). However, it is most likely that, in the majority of cases, the spirals are casts of inspissated endocervical mucus.

Figure 8-39 Curschmann's spirals in a cervicovaginal smear (see text).

Contaminants

The normal cervicovaginal smears may contain a variety of contaminants. **Lubricating jellies, vaginal creams, or powders may obscure the smears** completely and render it useless. Small **polygonal refractile crystals**, frequently seen in smears, usually originate from sterile powders used for surgical gloves. Other crystals, rarely occurring in smears, are **hematoidin crystals** or cockleburrs (Hollander and Gupta, 1974; Capaldo et al, 1983) and **"crystalline bodies,"** probably inspissated cervical mucus, described by Zaharopoulos et al (1985). Occasionally, **pollen** and **plant cells** may occur (Avrin et al, 1972). Plant cells are described in Chapter 19. **Grains of pollen** may be particularly disturbing. The spherical or oval grains come in various sizes depending on the plant of origin, and some may mimic epithelial squamous cells by size and configuration (Fig. 8-40). Some pollens may have a dense central core that may mimic a cancer cell (Fig. 8-40B,C). Pollen grains are best recognized by a rigid, translucent external envelope, best seen in Figure 8-40D, and lack of structure in the central core.

Other contaminants, such as fungus of the family *Alternaria*, may be observed (see Chap. 19 for description). Other rare contaminants include **larval parts of carpet beetles** (Bechtold et al, 1985), as well as other arthropods, and various protozoa may be occasionally observed (Fig. 8-41). Undoubtedly, from time to time, still other contaminants will be reported. The so-called **ciliated bodies**, reported in cervical smears and initially thought to be parasites, represent detached tufts of ciliated endocervical cells, described above and shown in Figure 8-21.

Ova

Way and Dawson (1959) and Carvalho (1965) reported the finding of an ovum in the vaginal smear. Carvalho's ovum was a spherical structure surrounded by a peripheral zone, interpreted as zona pellucida, and a peripheral array

P.217

of cells, presumably the corona radiata. Unfortunately, the measurements of the ovum were not provided. Although the identity of Carvalho's ovum was questioned by Norman (1975), Wachtel and Wytcherly (1970), and by Benson (1972), a recent photograph by Greenebaum (1998), illustrating a human oocyte (ovum) derived directly from an ovarian cystic follicle, confirmed Carvalho's observations. Greenbaum's oocyte was about 150 μm in diameter, had a tiny, barely visible nucleus, and it was surrounded by a transparent, striated zona pellucida (the product of the ovum) and a layer of follicular cells (Fig. 8-42).

Figure 8-40 Pollen in cervicovaginal smears. A-D. Pollen grains of various sizes. Note the sharply demarcated translucent capsule. In C, the grain of pollen is phagocytized by a macrophage. B and D mimic cancer cells because of the dark center.

Benign Cells Originating in Adjacent Organs

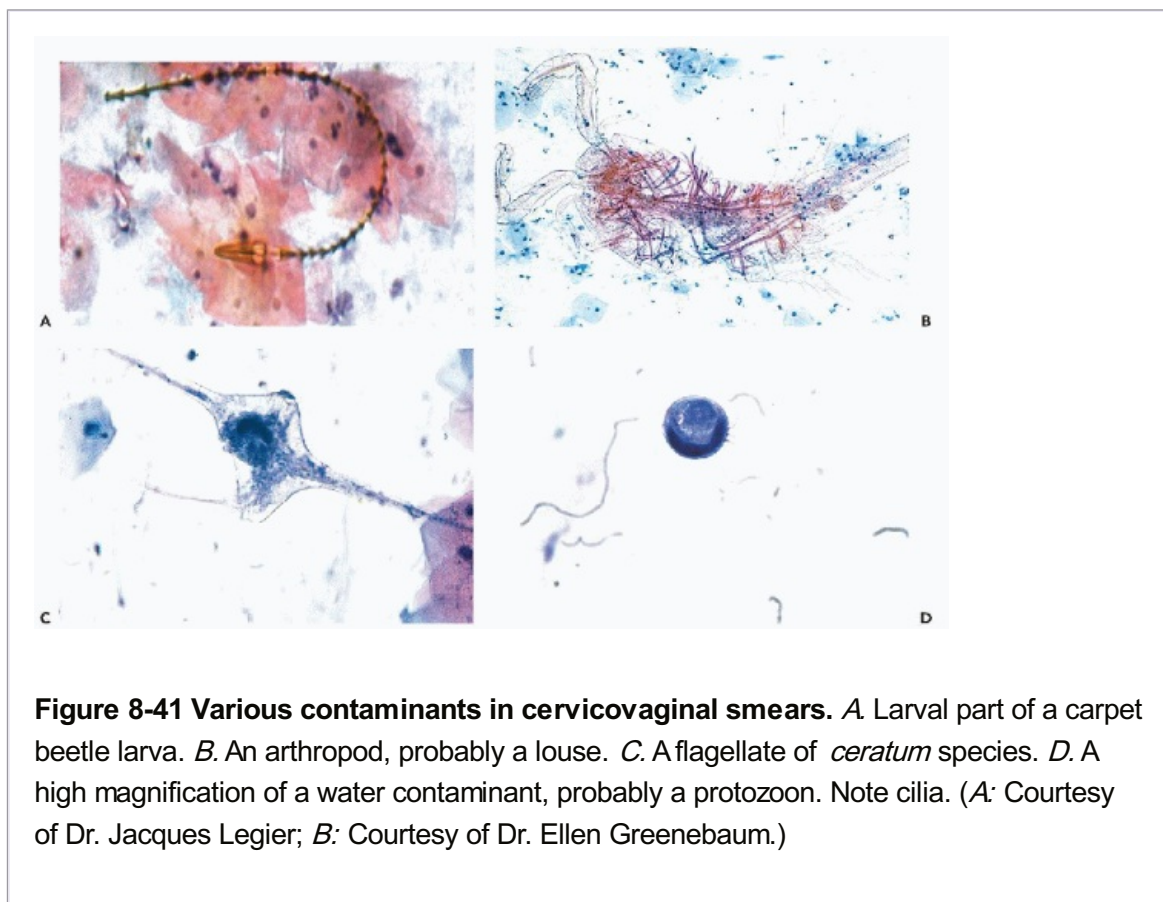

Cells from adjacent organs may be observed in vaginal smears and in endocervical and endometrial aspirates. The significance of these observations in reference to cancer is discussed in the appropriate chapters. Occasionally, however, benign cells of extraneous origin may be of diagnostic importance. Cells originating in the urinary bladder and in the colon, when

observed in gynecologic material, may indicate the presence of **vesicovaginal** or **rectovaginal fistula**. The identification of the **urothelial cells** of bladder origin may be difficult unless the multinucleated, large **umbrella cells** (see Chap. 22) are observed. Colonic cells, usually forming clusters or sheets of parallel cells, resemble endocervical cells, except for their larger size (Fig. 8-43A). Angeles and Saigo (1994) observed colonic cells in smears of 14 of 23 patients with rectovaginal fistula. Colon contents in the form of plant cells, characterized by a thick translucent cellulose membrane, may also be observed in such smears (Fig. 8-43B).

DEFINITION OF AN ADEQUATE CERVICOVAGINAL SAMPLE

The purpose of cytologic examination of the female genital tract is the detection of cancer and precancerous states, mainly of the uterine cervix. The question as to what constitutes an **adequate and representative cervicovaginal sample**, offering the best diagnostic opportunity, has been discussed for many years (see Koss and Hicklin, 1974). The issue has become important because the currently prevailing system of nomenclature, the Bethesda System (discussed in detail in Chap. 11), mandates the **reporting of inadequate samples** as a separate category. Severe medical and legal consequences may result from reporting such a sample as “negative” or “within normal limits,” particularly in the presence of a precancerous lesion or cancer of the uterine cervix. The issue of sample adequacy was relatively simple, so long as **direct cervical smears** were the dominant mode of examination, because the various components of the smear could be recognized. With the widespread use of **liquid monolayer, machine-generated preparations**, the issue became more complex.

Cervicovaginal Smears

A cervicovaginal smear should be representative of the squamous and endocervical epithelia of the uterine cervix, and include the transformation zone. A number of instruments, discussed in the Appendix to this chapter, have been introduced to improve the sampling of the uterine cervix. Therefore, **an adequate cervical smear should contain squamous cells from the vaginal portion of the uterine cervix, parabasal “metaplastic” cells, presumably derived from the transformation zone, and endocervical cells from the endocervical canal.** In practice, the composition of an adequate cervical smear **depends as much on the skill of the operator and the techniques used as on the age of the patient, because it depends on the location of the transformation zone.** As has been shown in Figure 8-10, the transformation zone in older women may be situated within the endocervical canal and will be much more difficult to sample than in a young woman. There is also some controversy as to

the significance of endocervical cells. Mitchell and Medley (1992, 1993), careful Australian workers, consider the presence of columnar cells as indispensable in the assessment of a smear as adequate. Kurman and Solomon (1992) suggested that the **minimum presence of endocervical cells should be two clusters, each composed of at least 5 cells**. In the 2001 Bethesda System, this requirement has been modified to "at least 10 well-preserved endocervical or squamous metaplasia cells, singly or in clusters" (Solomon and Nayar, 2004). Other observers question whether the presence of endocervical cells is essential (Koss and Hicklin, 1974; Metcalf et al, 1994; Koss and Gompel, 1999; Birdsong, 2001). This writer considers **the presence of cervical mucus equally important evidence of smear adequacy as the presence of endocervical cells**. The mucus, in the form of streaks containing cells desquamated from the endocervical canal, is an **invaluable diagnostic resource**. Unfortunately, with the use of endocervical brushes, which often require the removal of the plug of mucus from the external os, the presence of streaks of mucus can no longer be ascertained. The same is true of preparations of cervical cells collected in liquid samples. Therefore, the following **standards of smear adequacy are proposed for smears of women during the childbearing age**:

An adequate smear must contain:

Squamous cells from the portio of the uterine cervix

Parabasal "metaplastic" cells

A few endocervical cells or cervical mucus

Smears of prepubertal girls or postmenopausal women need not contain either endocervical cells or cervical mucus.

As Koss and Hicklin observed in 1974, **any smear containing abnormal cells and requiring further action is by definition adequate**, regardless of whether the above criteria are fulfilled or not. The same authors also noted that the **diagnostic accuracy of routine cervical smears, regardless of technique, is not absolute**. Therefore, **a minimum of three consecutive cervical smears, at intervals of 6 to 12 months, should be obtained before the patient is considered free of disease**. It was suggested that **subsequent screening may take place at longer intervals every other or third year**. The current guidelines of the American Cancer Society are in agreement with these recommendations.

Liquid Preparations

It is the occasional failure of the cervical smear, with its legal consequences, that led to the current trend to replace them with **liquid preparation systems**. At the time of this writing (2004), two commercially available automated smear-equivalent processing systems have been approved by the Food and Drug Administration in the United States, ThinPrep (Cytoc Corp., Marlborough, MA) and SurePath

P.220

(TriPath Corp., Burlington, NC). Both systems **require that the sample be placed in a container with fixative and processed by a machine that deposits an aliquot of cells in small circular areas of the slide**. The preparations are **relatively free of blood and debris, thus facilitating and accelerating screening, but also modifying somewhat the morphology of the cells and, thus, requiring special training in interpretation of material**. The two systems appear to be somewhat more efficient in the discovery of cellular abnormalities, as discussed in Chapters 12 and 13. A significant benefit of collection in liquid

fixative is the option of utilizing the **residual material for ancillary procedures**, such as the presence and typing of **human papillomavirus (HPV)**.

Still, the issue of **adequacy of liquid preparations has not been solved**. Because these preparations use only a small aliquot of the entire sample, the figure of 5,000 well-preserved squamous cells per preparation was suggested as evidence of smear adequacy (Solomon and Nayar, 2004). Such a sample would contain only a very small number of abnormal cells and, therefore, requires intense screening, obviating the principal advantage of liquid processing. Only longterm follow-up of patients will determine the accuracy of these cancer detection systems.

Appendix

CLINICAL PROCEDURES IN GYNECOLOGIC CYTOLOGY

The successful practice of gynecologic cytology depends to a large extent on good quality material secured from the genital tract. Therefore, it is recommended that the simple guidelines discussed below be followed before the sampling takes place. **The patient should not douche for 24 hours before the genital smears are obtained. During the childbearing age**, smears should be obtained at **mid-cycle**. Smears obtained during menstrual bleeding may be difficult to interpret because of contamination with blood, endometrium, debris, and macrophages (histiocytes).

Prior to sampling, it is important to **secure the necessary materials** and lay them out on a suitable, conveniently located surface within the reach of the operator:

- **Instrument(s)** used to obtain smears
- **Clean microscopic glass slides** of good quality, preferably with frosted ends (0.96-1.06 mm in thickness) for preparation of smears
- Suitable **pencil for slides with frosted ends** or, if **plain slides** are used, a **diamond marker** for identification of slides. Each slide should be identified with **patient's name, date, and/or identifying number**. **If separate samples are obtained from different organs of the female genital tract, the slides must be appropriately identified by symbols, for example, C = cervix, E = endocervix, EN = endometrium. The precise origin of each smear with the accompanying symbol must be noted on the laboratory form.**
- **Fixatives** (see below and Chap. 44)
- **Laboratory form** with clear identification of the patient and appropriate history. The minimum data required on each patient comprise:

Date of procedure

Name of physician or health facility submitting the sample

Patient's name, address, and ID number, if any

Sex and age

Source and site of origin of the specimen with identifying symbols (see above)

Method of collection

Presumed clinical diagnosis

Summary of prevailing symptoms

Prior treatment, if any

Prior cytology or histology

Date of last menstrual period

Contraceptive history

Obstetric history

PREPARATION OF SMEARS

Every effort should be made to place as much of the material obtained as possible on the slide and to prepare a **thin, uniform smear**. Thick smears with overlapping cell layers are difficult or impossible to interpret. Considerable skill and practice are required to prepare excellent smears by a single, swift motion without loss of material or air drying.

Fixation of Smears

Immediate fixation of smears facilitates correct interpretations. Two types of fixatives are commonly used—fluid fixatives and spray fixatives. Both are described in detail in Chapter 44 and, hence, only a brief summary is required here.

Fixatives

For all practical purposes, **95% ethyl alcohol or equivalent is a suitable universal fixative for routine smears**. Liquid fixatives can be used in Coplin jars with covers. Also, a pipette filled with the fixative may also be used to **fix the smear placed on a hard surface** for 15 minutes or more, making sure to **replenish the fixative to prevent drying caused by evaporation**. The fixed slides may be placed in an appropriate cardboard or plastic container for shipment to the laboratory. Certain commercially available fixatives, particularly **CytoRichred** (TriPath Corp., Burlington, NC) has found many uses in preparation of endometrial smears, as discussed in Chapters 11 and 12 (Maksem and Knesel, 1995). The fixative preserves cells of diagnostic value while lysing erythrocytes.

Spray fixatives contain water-soluble polymers or plastics

P.221

and are described in detail in Chapter 44. When correctly used, spray fixatives **protect the smears from drying** by forming an invisible film on the surface of the slides. If spray fixatives are selected (and they usually are easier to handle than liquid fixatives), they should be applied **immediately** after the process of smear preparation has been completed. Correct use of the spray fixatives calls for several precautions:

Figure 8-44 Use of coating fixatives for smears of uterine cervix obtained with a wooden spatula. Immediate application of fixative is essential. (Clay-Adams Inc., New York, NY.)

- The spray must be **smooth and steady** and the operation of the nozzle must be checked before the smear is obtained.
- The **distance between the nozzle of the spray and the smear to be sprayed must be about 10 to 12 inches (25 to 30 cm)**, as shown in Figure 8-44. If the spray is held too close to the smear, several mishaps commonly occur; the cells may be dislodged by the force of the spray, or the evaporation of the spray vehicle may freeze and irreversibly damage the cells. An artifact may also occur, inasmuch as normal squamous cells may acquire a perinuclear halo, rendering them similar to human papillomavirus-infected cells or koilocytes. If the nozzle is too far from the target, insufficient fixative will reach the surface.
- **Smears coated with spray fixative are air dried** and placed in cardboard slide containers and forwarded to the laboratory.
- Although there is no evidence at this time that the materials contained in the various spray preparations are harmful, it is advisable to protect the patient and the medical personnel from inhalation of the spray by using a face mask or by performing the spraying procedure under a protective glass plate or a laboratory hood.

Inexpensive liquid-coating fixatives may be prepared in the laboratory and used in lieu of spray fixatives. Carbowax fixative, described in Chapter 44, is an example. A few drops of this fixative are placed on the surface of the smear. After drying (5 to 10 minutes), the slides may be placed in slide containers for shipment to the laboratory.

COLLECTION OF MATERIAL FOR LIQUID PROCESSING AND “MONOLAYER” SMEARS

If processing by an **automated apparatus** is selected, the container with the company-recommended fixative should be available. The companies provide vials with fixatives

accommodating collection devices or cell samples. For further discussion of these options, see Chapter 44.

SAMPLING SYSTEMS

Vaginal Smear

The original method, on which Papanicolaou and Traut based their initial observation in 1942, was the vaginal smear (see Chaps. 1, 11, and 13 for a detailed account of these events). Nowadays the procedure is rarely used, because it is **not efficient in the discovery of precancerous lesions of the uterine cervix** and requires time and skill in screening. The vaginal sample is often very rich in cells and difficult to interpret and, hence, not labor-effective.

The advantage of the vaginal smear lies chiefly in the **ease** with which it is obtained, even in the presence of an intact hymen. In **women past the age of 40**, the vaginal smear complements the cervical sample and may **contain important information pertaining to the endometrium, fallopian tubes, and the ovaries** and, occasionally, from **other, more distant sites** (see Chaps. 13 and 14). Therefore,

P.222

in my judgment, it should be maintained in the armamentarium of cancer detection in older women. This smear is best obtained as the **first step in the gynecologic examination**, prior to introduction of the speculum. The patient is placed in a lithotomy position. The posterior fornix of the vagina is aspirated with the blunt end of a slightly curved **glass pipette** fitted with a rubber bulb. During aspiration, the end of the pipette should be gently moved from side to side to ensure a good sampling of cells. Alternately, a **tongue depressor or similar simple device** may be used to collect cells from the posterior vaginal fornix. The material is spread rapidly on a clean glass slide, which is fixed without delay. **A vaginal smear alone should never be considered as a sufficient cytologic sample in women with intact uteri and it must be accompanied by a cervical sample.**

The **vaginal smear for hormonal studies** should be obtained by scraping the **lateral wall of the vagina** at some distance from the cervix. These smears are reliable in the evaluation of the hormonal status of the woman in the absence of inflammation or hormonal treatment, as discussed in Chapter 9.

Figure 8-45 Instruments for sampling of the uterine cervix.

Cervical Smears

The cervical smear and its variants are utilized for diagnosis of precancerous lesions and cancer of the uterine cervix. Regardless of the instrument used, the cervical smear must be obtained **under direct vision after introduction of the unlubricated speculum**. If there are difficulties in introducing the speculum, a few drops of normal saline solution may be used to moisten it. **Several methods and instruments for securing cytologic material from the uterine cervix are available (Fig. 8-45). Although many are no longer used, they are generally much less expensive and more affordable in developing countries.**

Nonabsorbent Cotton Swab Smear

This inexpensive and simple mode of sampling the uterine cervix is no longer recommended because of loss of cells adhering to the cotton.

Cervical Scraper or Spatula

As initially proposed by Ayre (1947), a wooden tongue depressor, cut with scissors to fit the contour of the cervix,

P.223

may be used. Commercial plastic scrapers are now widely available. The end of the scraper is

U shaped, with one arm longer than the other. The scraper should fit the contours of the cervix, particularly the squamo-columnar junction, with the longer end introduced into the endocervical canal. The scraper is rotated 360° under pressure, the longer end being used as a pivot within the external os (see Fig. 1-4). The material is spread on a slide and fixed immediately. Abundant and diagnostically valuable material is obtained by this method. The method may occasionally be traumatic to the patient and may cause some minor bleeding.

Triple-Smear Method (VCE Smear)

Although now very rarely used, the method, described by Wied and Bahr (1959), advocates placing material from three sources (vagina, portio, and endocervix) on a single, specially prepared and etched glass slide. The method requires considerable dexterity on the part of the clinician to obtain material rapidly in order to avoid drying of smears.

Endocervical Brushes

Because of the insistence that an adequate cytologic sample must contain endocervical cells, several types of endocervical brushes for sampling of the cervix have been introduced. The advantage of these instruments was based on the concept that an adequate cervical smear must contain endocervical cells and that the brushes increase the yield of endocervical lesions, a concept supported by the Bethesda System (see above and Chap. 11). Such brushes must be introduced into the endocervical canal under visual control and gently rotated to provide adequate material. In the process, **the plug of cervical mucus, usually present at the external os, is displaced and lost, although it is an important source of abnormal cells** (see above and Chap. 11). Except in postmenopausal women with atrophy of the uterus, the endocervical brush yields endocervical cells in virtually all the smears, rendering them "adequate." However, in smears prepared from endocervical brushes, the thick clusters of endocervical cells, scraped from the endocervical surface, may be difficult to interpret. There is also evidence that many patients experience bleeding or spotting after the use of these instruments. **The endocervical brushes serve only for the sampling of the endocervix and must be supplemented with a scrape smear of the exocervix.**

Brushes Combining Endocervical and Exocervical Sampling

The prototype of such an instrument is the Cervex brush (Rovers Medical Devices, distributed by Therapak Corp. Irwindale, CA), which consists of a flat array of flexible plastic strips. The central strips are longer and, thus, enter the endocervical canal. Several rotations of the instrument ensure **sampling of the entire cervical epithelium with adequate representation of endocervical and squamous cells.** There are several **variants of the original Cervex brush**, one shown in Figure 8-45 (CytoPrep Inc., Eschen, Lichtenstein). These instruments have been recommended as a single sample for use with the liquid collection for automated processing of samples.

Self-Administered Sampling of the Female Genital Tract

Vaginal Tampon

In the 1950s, a vaginal tampon, composed of compressed cotton enclosed in a nylon cover, the first self-administered device for cervical cancer detection, was developed by Draghi and tested by Brunschwig (1957) and by Papanicolaou (1954). Bader et al (1957) compared the performance of the tampon with simultaneously obtained vaginal and cervical smears in 2,691

asymptomatic patients. The quality of the smear, obtained by stamping the tampon on a microscopic slide, was judged to be **adequate** in about two-thirds of the patients. The tampon smears were considered negative in about half the patients with carcinoma in situ, diagnosed on cervical smears, and the device has never been accepted as a viable substitute of the direct cervical sample.

Self-Administered Pipette

Koch and Stakemann (1962) and Davis (1962) introduced a **self-administered pipette** for collection of cytologic material for purposes of cervix cancer detection that can be mailed to the patient, accompanied by a set of simple instructions. The disposable device consisted of a fixative-filled plastic bulb attached to a pipette. The patient inserts the pipette into the vagina and, by compressing the elastic bulb, expresses the fixative. The bulb is then released and the fixative, plus the collected cells, is aspirated back into the pipette. The pipette is sealed and mailed back to the laboratory. The fluid is spun down in a centrifuge and the sediment smeared on two or more slides. Residual material may be kept indefinitely. Davis considered 50 to 100 cells per low-power field as an adequate smear. The screening of this material was time-consuming because abnormal cells were few. In many ways, the material obtained by irrigation resembles a diluted vaginal smear. The device was evaluated by several independent observers with mixed results. Richart (1965) pointed out that irrigation smears failed to reveal 40% to 50% of early neoplastic lesions of the cervix. A similar result was reported by Muskett et al (1966) on a smaller group of carefully controlled patients. Reagan and Lin (1967), Mattingly et al (1967), Anderson and Gunn (1967), Carrow et al (1967), and Husain (1970) rendered reports ranging from highly skeptical to enthusiastic. It is generally considered that, unless the patient has no access to a more direct method of cytologic sampling, self-administered smears should not be recommended because of poor accuracy and because they deprive the patient of a clinical examination.

It is of interest that a **similar self-administered device was recently evaluated as a means of sample collection for analysis of human papillomavirus** (Wright et al, 2000).

P.224

Endometrial Sampling

The methods are described in Chapter 13.

Cytologic Evaluation of Menstrual Disorders and Hormonal Abnormalities

PRINCIPLES

The established approach to the evaluation of ovarian function and endocrine disorders in the woman is based on serial biochemical analyses of hormones, such as estrogen, progesterone, luteinizing hormones and their metabolites (Albertson and Zinaman, 1987). More recently, the analysis of hormonal substances that participate in embryonal development of gonads has contributed still further to the clarification of endocrine disorders. For example, the measurements of the müllerian-inhibiting substance, a hormone that promotes the involution of the müllerian duct and thus enhances the development of male characteristics, allowed the discrimination between male children with a congenital absence of testes (anorchia) and undescended testes (Lee et al, 1997). In children suspected of other congenital abnormalities, molecular-genetic analyses may be performed. For example, in children with congenital adrenal hypoplasia, who may also display underdevelopment of gonads, a mutation of the responsible gene located on the X chromosome could be documented (Merke et al, 1999). Many additional such examples could be cited. In women who suffer from menstrual disorders and abnormalities of the ovarian cycle, the biochemical analyses can be effectively supplemented by the old-fashioned endometrial biopsies, or studies of endocervical mucus (Lotan and Diamant, 1978). In addition, the **cervicovaginal smear may sometimes provide useful information and has the advantage of being easy to obtain, rapidly evaluated, and inexpensive.** The cytologic approach is particularly valuable if laboratories specializing in endocrine analysis are not readily available. The **principle**

P.228

of the cytologic hormonal analysis is simple. The degree of maturation of the squamous epithelium of the female genital tract depends on steroid hormones, mainly estrogen. Estrogen receptors are present in the squamous epithelium of the uterine cervix and vagina, particularly in the basal cells (Press et al, 1986; Kupryjanczyk and Moller, 1988), and are expressed more strongly during the proliferative phase of the cell cycle than during the secretory phase, accounting for the observed changes in epithelial maturation. Therefore, the **quantitative relationship of squamous cells of varying degree of maturity in a cervicovaginal smear may serve as an index of the hormonal status of the female. In some cases of congenital abnormalities, the analysis of sex chromatin bodies (Barr bodies) in the same smears may yield valuable information.**

It is beyond the scope of this book to discuss all the variants and metabolites of the steroid hormones. For the sake of simplicity, and because of their impact on cervicovaginal cytology, the key hormones and their activity to be discussed are estrogen, progesterone, and

androgenic (masculinizing) hormones.

MECHANISMS OF FORMATION OF STEROID HORMONES

The main function of steroid hormones in the woman is to induce ovulation and prepare the uterus for pregnancy. The regularity with which this process occurs during the childbearing age of a normal woman is astounding and as yet not fully understood. As was summarized in Chapter 8 and Figure 8-18, the formation of steroid hormones by the ovary is governed by polypeptide hormones of pituitary origin (follicle-stimulating hormone [FSH] and luteinizing hormone [LH]). The ovary synthesizes the steroid hormones, which act on the endometrium, squamous epithelium, and other target cells in the uterus.

Mechanisms of Action of Pituitary Hormones on Ovarian Target Cells

The first sequence, which has for its purpose the formation in the ovary of various steroid hormones such as estrogen and progesterone from cholesterol, may be briefly summarized as follows:

- Pituitary peptide hormone binds to the receptors on the membrane of ovarian cells with endocrine function, stimulating an increased activity of a common mediator, adenylate cyclase. Adenylate cyclase stimulates the synthesis of 3'5'-adenosine monophosphate (cyclic AMP or cAMP) from adenosine triphosphate (ATP).
- cAMP activates the appropriate protein kinase leading to the formation of an enzyme, cholesterol esterase, and other enzymes involved in the biosynthesis of steroid hormones.

Mechanisms of Formation of Steroid Hormones in the Ovary

- The cholesterol esterase leads to an increased accumulation of free cholesterol as a precursor for steroid biosynthesis.
- Free cholesterol is transformed by enzymes into steroid hormones in the smooth endoplasmic reticulum of the appropriate ovarian cells. **Estrogen is produced by the follicular cells of the maturing ovarian follicles.** After ovulation, **progesterone is produced by cells of the corpus luteum.** For a recent review of the mechanisms of formation of steroid hormones in the pituitary and the gonads, see Adashi and Hennebold (1999).

Effect of Steroid Hormones on Target Cells

Ovarian steroids, such as estrogen and progesterone, interact with cells in the endometrium and the squamous epithelium of the cervix and vagina and the smooth muscle of the uterus. This sequence may be briefly summarized as follows:

- The steroid hormone binds to a specific cytoplasmic receptor protein in the cells of the target organ and enters the cytoplasm. As has been recently reported, there are at least two types of estrogen receptors with complex patterns of function (McDonnell and Norris, 2002).
- Steroid protein complex enters the nucleus and binds to the DNA specific receptor. Messenger RNA is formed.
- Messenger RNA enters the cytoplasm, binds to ribosomes and leads to the synthesis of specific proteins, such as enzymes or structural proteins, that are expressed in the cytoplasm of the target cell.

Nuclear receptors for estrogen and progesterone have been identified and sequenced.

Recent investigations shed light on the regulation of hormonal receptors in various target cells (McDonnell and Norris, 2002). This led to the development of specific antibodies that can be used to visualize the presence of these receptors in the nucleus by means of immunofluorescence or an immunocytochemical approach using the peroxidase-antiperoxidase reaction that forms visible precipitates. The precipitates can be measured by image analysis and related techniques (Bacus et al, 1988). This system of **steroid receptor identification and quantitation** has been extensively used in the assessment of mammary carcinoma (see Chap. 29), but its applicability to the cells of the female genital tract has been limited.

The effects of estrogen and progesterone on the endometrium and endometrial cells are discussed in Chapter 8. In this chapter, the effect of these and other hormones on the squamous epithelium of the female genital tract will be discussed.

THE EFFECT OF STEROID HORMONES ON SQUAMOUS EPITHELIUM OF THE FEMALE GENITAL TRACT

Smear Patterns

Naturally occurring **estrogen**, or the **parenteral administration of estrogen or its natural or synthetic substitutes**

P.229

in adequate amounts, produces a rapid and complete maturation of the normal squamous epithelium of the female genital tract with a resulting preponderance of mature superficial squamous cells in smears. The effect takes place regardless of the prior hormonal status, **except during pregnancy**. Conversely, **complete atrophy of the squamous epithelium of the vagina and cervix may be equated with complete absence of estrogenic activity**. However, there are **no reliable data linking intermediate degrees of maturation of the squamous epithelium with the action of a specific hormone or hormones**. Thus, partial or incomplete maturation of the squamous epithelium may have various causes, such as an inadequate or low supply of estrogen and its derivatives; an effect of antagonistic hormones, such as progesterone or androgenic hormones; or the effect of some of the widely used estrogen agonists, such as tamoxifen; or to a combination of these and probably other factors. The fact that surgical castration does not necessarily lead to complete atrophy of the squamous epithelium strongly supports the possibility that **extragenital hormonal factors**, such as **adrenal hormones**, are capable of influencing the squamous epithelium of the genital tract of the female.

It is obvious, therefore, that the patterns of squamous cells should be interpreted cautiously in terms of endocrine status or therapeutic indications. Unfortunately, rigid diagnostic standards in this area of genital cytology are difficult to establish and, consequently, the literature is replete with contradictory statements. This is well illustrated by the problem of cytologic evaluation of pregnancy at term, discussed in Chapter 8. Nonetheless, in specific clinical situations, discussed below, endocrine cytology is a valuable guide to diagnosis and treatment.

Hormonal Cytology in Various Age Groups

Evaluation of the endocrine status of a menstruating woman **during the childbearing age** belongs among the most difficult tasks in diagnostic cytology. There is **considerable variation in the smear patterns from one patient to another**, even if matched for age and menstrual history. Furthermore, there is **considerable variation from cycle to cycle in the same**

patient. Daily variations and even variations between simultaneously obtained smears may occur. **Even the mere effect of smear-taking may influence the pattern of the following smear** by increasing the vascularity of the epithelium.

However, hormonal evaluation of the smears may be of substantial assistance in situations associated with **amenorrhea or other significant disturbances of the menstrual cycle** and may be of value in determining the **time of ovulation** for **artificial insemination or in vitro fertilization** (see below).

Evaluation of the endocrine status in **prepubertal and postmenopausal patients** is an easier and more rewarding task than during the childbearing age. In a patient whose baseline smear shows complete atrophy, an increased maturation of the squamous epithelium is easy to assess. Still, even the procedure of smear-taking may reduce the dryness of the vagina and result in a less atrophic smear pattern. In the absence of atrophy, some of the problems described above for women in the childbearing age may also preclude an accurate cytologic evaluation of hormonal effect.

The Influence of Factors Other Than Hormonal on Endocrine Evaluation of Smears

Several factors other than endogenous or exogenous hormones may influence the status of the squamous epithelium.

Inflammatory Processes

As is described in Chapter 10, inflammatory processes, particularly *Trichomonas vaginalis* infestation, may result in increased maturation of squamous cells in postmenopausal women. Histologic and colposcopic evidence suggests that increased vascularity of the epithelium may be a factor in this process. Other inflammatory processes, particularly coccal bacterial infections, may obscure the smear pattern because of pus formation. Therefore, **it is advisable to forego any attempts at estimation of maturation of squamous cells in the presence of a marked inflammatory process.**

Cancer

In postmenopausal women with **carcinoma of the uterine cervix or endometrium**, abnormally high levels of maturation of the squamous epithelium may be observed. Although in endometrial cancer this may represent a hormonal effect, in cervix cancer the effect is probably due to inflammation (Cassano et al, 1986).

Cytolysis

Cytolysis caused by *Lactobacillus* (the Döderlein bacillus) or related organisms may destroy squamous cells in sufficient numbers to preclude any reasonable estimation of level of maturation (see Chaps. 8 and 10). **The effects of hormones and other drugs** precluding the assessment of the hormonal status are discussed below.

Radiotherapy, Surgery and Other Interventions

Radiotherapy to the vagina or cervix exercises marked immediate and long-term effects on smear patterns, as discussed in Chapter 18. It is evident that radiotherapy, with its protracted and significant influence on the biology of the squamous epithelium, restricts the possibility of subsequent estimation of hormonal activity by smears. **Surgery, cauterization, and other**

forms of treatment of diseases of the vagina or cervix also preclude proper hormonal evaluation **until the healing has become complete**—usually no fewer than 6 weeks after the procedure.

TECHNIQUES IN THE CYTOLOGIC EVALUATION OF THE HORMONAL STATUS

Vaginal Smears

Several conditions must be fulfilled before a successful hormonal evaluation of the squamous epithelium may be undertaken.

P.230

- There must be absence of inflammation or cytolysis.
- There must be no recent medication, either topical or systemic, especially with compounds known to affect the squamous epithelium of the lower genital tract.
- There must be no history of radiotherapy or recent surgery to the vagina or cervix.
- An adequate baseline investigation must have been performed in menstruating women. This should include daily smears during at least one and preferably two complete cycles, or their chronologic equivalent. In nonmenstruating patients, two or three smears may suffice.
- **The smears should be obtained from the proximal portion of the lateral wall of the vagina, care being taken to avoid contamination with material from the adjacent cervix.** Soost (1960), in an elaborate study, confirmed that this is the area of the vagina most accurately reflecting the hormonal status. The squamous epithelium of distal vagina or of the cervix shows a lesser response to hormonal stimulation.

Although **routine cervicovaginal smears are less accurate for purposes of hormonal evaluation**, their use cannot be unequivocally condemned because the patterns of maturation of squamous cells may provide useful information either in the presence of a marked estrogenic effect (dominance of mature squamous cells in smears) or complete absence thereof (atrophic smear pattern).

Urocytograms and Other Methods

A number of observers, starting with Papanicolaou (1948), and subsequently Lencioni et al (1969, 1972), Haour (1974), and O'Morchoe (1967), reported results of hormonal evaluation with the use of an “**urocytogram**,” which is the **evaluation of squamous cells in smears obtained from the sediment of voided urine**. It is not completely clear whether the squamous cells in the urinary sediment are a contaminant with cells of vaginal origin or whether they reflect the presence of squamous epithelium of vaginal type that may be observed in the bladder trigone of many women (see Chap. 22). The urinary sediment has the advantage of easy collection without the necessity of a gynecologic examination and is **particularly useful in the evaluation of some endocrine disorders in infants and children**.

Other methods of endocrine evaluation include smears obtained from the inner aspect of labia minora of the vulva, as suggested by Tozzini et al (1971).

In congenital disorders in which X chromosome may be affected, the evaluation of sex chromatin bodies is conveniently performed in vaginal smears just as in scrape smears of the oral mucosa. Although this is not the primary topic of this chapter, it must be mentioned here that **endometrial biopsies** offer important information on ovulation and disturbances of the menstrual cycle. For further discussion of this topic, see Chapter 13.

OBJECTIVE EVALUATION OF HORMONAL PATTERNS

The Indices of Squamous Cells

To confer numerical reproducibility upon hormonal evaluation, several indices defining the status of the squamous cells in a smear have been advocated.

The Karyopyknotic Index (KI)

The karyopyknotic index expresses the **percentile relationship of superficial squamous cells with pyknotic nuclei to all mature squamous cells**. Usually, 200 to 400 consecutive cells in three or four different fields on the smear are evaluated. According to Pundel (1966), in a normally menstruating woman, the peak of KI usually coincides with the time of ovulation and was estimated at 50% to 85%. Variation from patient to patient is considerable. Schneider et al (1977) found a statistically significant correlation between KI and plasma estradiol levels as measured by radioimmunoassays.

The Eosinophilic Index (EI)

The eosinophilic index expresses the **percentile relationship of mature squamous cells with eosinophilic cytoplasm to all mature squamous cells**, regardless of the status of the nucleus. The procedure is similar to that described for the karyopyknotic index. Often the simple **Shorr's stain** (see Chap. 44) is used in preference to Papanicolaou stain. Pundel (1966) reported that in a normal menstruating woman, the peak of EI coincides with the peak of KI and may reach 50% to 75% at the time of ovulation.

The Maturation Index (MI)

The maturation index, first described by the Czech investigator, Nykliček in 1951, expresses the maturation of the squamous epithelium as a **percentile relationship of parabasal cells to intermediate cells to superficial cells**. The count should be performed on single cells. Cell clusters must be avoided. For example, in a normal menstruating woman at the time of ovulation, an MI of 0:35:65 would indicate that the smear contained no parabasal cells, 35% of intermediate cells, and 65% of superficial cells. A postmenopausal patient with marked atrophy would have a MI of 90:10:0, indicating marked preponderance of parabasal cells. Reyniak et al (1971) found good correlation between the MI and endometrial biopsies for staging of the menstrual cycle. Estrogen-type smear corresponded to proliferative endometrium in 83% of cases, and the premenstrual type of smear corresponded to secretory endometrium in 88% of cases. On the other hand, Schneider et al (1977) found a poor correlation between MI and plasma estradiol levels.

The Maturation Value

Meisels (1967) suggested that a specific numerical value be attached to the three principal subgroups of the squamous cells—a value of 1.0 to superficial squamous cells, a value of 0.5 to intermediate cells, and a value of 0.0 to parabasal cells. The maturation value (MV) would be expressed by

P.231

multiplying the percentage in each cell category by its assigned value. For example, the MV for the two patients discussed above under MI would be as follows:

Patient 1 with MI 0:35:65 (normal menstruating woman at time of ovulation)

$$\begin{array}{r}
 0 \times 0 = 00.0 \\
 35 \times 0.5 = 17.5 \\
 65 \times 1.0 = \underline{65.0} \\
 \text{MV} = 82.5
 \end{array}$$

Patient 2 with MI 90:10:0 (woman with postmenopausal atrophy)

$$\begin{array}{r}
 90 \times 0 = 0 \\
 10 \times 0.5 = 5 \\
 0 \times 1.0 = \underline{0} \\
 \text{MV} = 5
 \end{array}$$

This system gives a single figure from zero to 100 to express the hormonal status of the patient and, thus, offers advantages for computerized handling of data. **An MV of 100 indicates a pure population of superficial squamous cells, MV of zero indicates a pure population of parabasal cells.** For menstruating normal women, the MV is between 50 and 95; for women with varying degrees of atrophy of squamous epithelium, the MV is below 50.

Other Indices

The **folded-cell index** represents the relationship of mature superficial or intermediate squamous cells with folded cytoplasm to all mature squamous cells. The **crowded-cell index** represents the relationship of mature squamous cells lying in clusters of four or more cells to all mature squamous cells.

The reader is referred to several papers by Wied et al (1968, 1992) listed in the bibliography for additional information on the various indices.

Critique of Indices

In an extensive study, Cordoba (1964) pointed out that any indices based on a single smear are not reliable. Even several smears obtained on the same day yield an error of 20%, if 1,000 cells are evaluated. This critique is valid in my experience. Particularly vulnerable is the eosinophilic index, because it is known that even a short exposure to air may significantly increase the proportion of cells with eosinophilic cytoplasm. The most reasonable of the indices is the maturation index and its derivative, the maturation value, since it gives an idea of the make-up of the squamous epithelium. However, to obtain results that would withstand a critical statistical analysis, at least 500 single cells, dispersed in four quadrants of the smear, should be counted, surely a time-consuming procedure.

Alternative Ways of Reporting Hormonal Status

It has been my practice to base the evaluation of the maturation of the squamous epithelium on an **overall visual impression gained during the routine screening of smears**. Dr. George Wied has suggested the term **estimogram** for this procedure. This simplest of methods has not failed in revealing major abnormalities of smear patterns. By comparing the current smear pattern with original baseline smears, a good appreciation of changes in smear pattern may be gained. Small variations in smear pattern have no diagnostic meaning but may strongly influence the indices and thus give a false impression of hormonal "effects." The reporting of smears based on this overall visual impression is always given in reference to age, menstrual

history, and possible clinical significance. Some examples follow:

- Patient age 35: "Midcycle smear pattern—consistent with functioning ovaries."
- Patient age 52: "Absence of maturation of squamous cells consistent with menopause."
- Patient age 25: "Absence of maturation of squamous cells—abnormal for age."
- Patient age 60: "High level of maturation of squamous cells not consistent with clinical menopause. It is assumed that this patient is not receiving estrogens or other drugs that may account for this smear pattern."

DETERMINATION OF THE TIME OF OVULATION FROM CERVICOVAGINAL SMEARS

A precise determination of the time of the ovulation is important in **artificial insemination** and in **in vitro fertilization**, which incidentally is also valuable in animal husbandry. Hormonal patterns of cervicovaginal smears were used as a guide for embryo transfer in in vitro fertilization with fair results (Bercovici et al, 1988). Boquoi and Hammerstein (1969) reported that vaginal hormonal cytology **correlated poorly** with hormonal patterns of urinary steroid hormone secretion in patients in whom **ovulation was induced with clomiphene citrate**. **The use of the cervicovaginal smears to establish the time of ovulation or the status of the endometrium has been of limited reliability** in the author's hands. Under the best of circumstances, the timing of the highest count of flat superficial squamous cells, reflecting the peak of estrogen activity just prior to ovulation, requires the analysis of two or more cycles. Furthermore, in some patients, particularly in those with disturbances of ovarian function, the ovulation pattern may not occur, or the change may be insignificant and difficult to assess. **It is, therefore, recommended that cytologic methods for estimation of ovulation or status of the endometrium be supplemented by other procedures, such as temperature curves and endometrial biopsies.** The examination of endocervical mucus may also be of assistance. Cyclic changes in the physicochemical properties of the cervical mucus have been known for a great many years. Prior to ovulation, the mucus tends to be viscous and when placed on a glass slide, form crystalline, **fern-like structures**, whereas at the time of and after ovulation, the mucus is more liquid and does not crystallize (see Chap. 8). Occasionally,

P.232

crystallized mucus may be observed in cervical smears.

As discussed in Chapter 8, it has been suggested by Affandi et al (1985) that the **endocervical cells participate in the cyclic menstrual changes** and that their **morphology reflects the proliferative and secretory phases of the endometrium**. During the preovulatory proliferative phase of the cycle, the endocervical cell cytoplasm is opaque and the nuclei spherical. During the postovulatory secretory phase, the endocervical cells obtained on the 20th day of the cycle displayed abundant, clear cytoplasm and nuclear "distortion" or "nipples." If the ovulation has not taken place, the cytoplasm of the endocervical cells remains opaque, and the nuclear "nipples" do not appear. Although anecdotal observations support the concept, the method has not received critical evaluation.

CYTOLOGIC EVALUATION OF MENSTRUAL DISORDERS

Cytologic hormonal evaluation may be of assistance in the evaluation of **amenorrhea (cessation of menses)**, in women who have never menstruated (**primary amenorrhea**) or who stopped menstruating at a young age after a period of normal menses (**secondary**

amenorrhea). The most obvious cause of temporary secondary amenorrhea is **pregnancy**, which was discussed in Chapter 8. Hormonal cytology is of little help in the evaluation of abnormal bleeding, such as **meno- and metrorrhagias**.

Amenorrhea

In primary or secondary amenorrhea, a vaginal smear may be of value in determining **whether the disorder is due to an absence of ovarian function or to other factors**. A smear that **fails to show any evidence of maturation of squamous cells indicates an absence of ovarian activity**. This disturbance may be due to a **primary ovarian deficiency** or a **failure of the pituitary**, known as **Simmond's disease**. Patterns with partial maturation of squamous cells suggestive of some measure of ovarian activity, may also be associated with amenorrhea. On the other hand, **normal maturation of squamous epithelium indicates the presence of ovarian function** that is sometimes vested in undescended testes (see below). Disturbances of the menstrual cycle due to excessive activity of hormones with estrogenic effect will be discussed below.

Primary Amenorrhea

In many of the patients who have never menstruated, there is a **major congenital disorder of their reproductive apparatus**. Some of these patients have a **congenital absence of the uterus** or a **congenital deficiency of the pituitary gland**. Others, although provided with **female external genitalia and female secondary sex characteristics**, may be either **genetic males** or have **no genetic sex at all**; in the cells of such patients, the **sex chromatin (Barr body) will be absent**. Hence, in the cytologic investigation of patients with primary amenorrhea, **the presence or absence of Barr bodies must be ascertained, together with the estimation of the level of maturation of the squamous epithelium**. The vaginal smear is an excellent medium, serving both purposes. Table 9-1 summarizes the pertinent cytologic findings in this group of patients.

Gonadal Dysgenesis: Turner's Syndrome

Patients with this congenital disorder have **only 45 chromosomes because one of the X chromosomes is absent**. This chromosomal pattern is designated as **XO** (see Chap. 4). The disorder is found with considerable frequency in spontaneously aborted products of conception. Most surviving patients are of short stature, have a short webbed neck, and their arms and forearms form a wide angle (known as *cubitus valgus*). The patients have a vagina and poorly developed female breasts. The uterus, if present, is rudimentary and the gonads are absent or represented by a band of fibrous tissue or streaks. Other congenital abnormalities, such as coarctation of the aorta, multiple pigmented nevi, and renal anomalies, may occur, as initially described by Turner (summary in Sanger, 1996). These patients do not menstruate. The cervicovaginal smears of such patients **fail to show any maturation of the squamous epithelium and thus mimic the pattern of epithelial atrophy of advanced menopause**. **Sex chromatin is absent**. This type of vaginal smear is unique and diagnostic of this disorder (Fig. 9-1).

Other Forms of Gonadal Dysgenesis

Variants of gonadal dysgenesis, such as XO-XY mosaicism or XX with gonadal streaks have been described in patients with female phenotype, a vagina, and occasionally an enlarged penis-like clitoris. The patients do not menstruate. The smear pattern and the presence of sex

chromatin **depend on the karyotype**. In patients with XX karyotype, there may be some maturation of squamous cells and the sex chromatin is usually present. In mosaics, its presence is variable. In genetic males in whom rudimentary testes can be observed, the sex chromatin is absent.

TABLE 9-1 PERTINENT CYTOLOGIC FINDINGS IN PRIMARY AMENORRHEA

	Epithelial Maturation	Sex Chromatin
Turner's syndrome	Absent	Absent
Other forms of gonadal dysgenesis	Variable	Usually absent
Syndrome of feminizing testes	Present	Absent
Pituitary insufficiency	Variable	Present
Congenital absence of uterus	Normal	Present

P.233

Figure 9-1 Turner's syndrome. Cervicovaginal smear in a 26-year-old woman with XO karyotype. Note absence of maturation of squamous cells and of sex chromatin (Barr) bodies.

The Syndrome of Feminizing Testes (Male Pseudohermaphroditism)

In this uncommon disorder, the patients are **genetic males** with 46 chromosomes (XY). The

patients have either **undescended or partly descended testes, which produce female sex hormones** and accordingly induce both primary and secondary female sex characteristics, except for the **absence of the uterus and, hence, absence of menses**. A congenital error in testosterone biosynthesis has been documented in these patients. The cervicovaginal smears **fail to show any sex chromatin** but the level of maturation of the squamous epithelium is significantly better than that in gonadal dysgenesis, occasionally reaching full maturation (Rakoff, 1961). Because there is danger of the occurrence of a malignant tumor (seminoma) in the undescended testes, surgical ablation of the gonads is often performed in this condition. Subsequently, parenteral therapy with estrogens is used to supplant the removed source of hormones. **The cervicovaginal smear is an excellent means of following the effects of treatment on these patients.**

In passing, it must be noted that another **genetic abnormality in males, the Klinefelter's syndrome**, may also be recognized by cytologic techniques. **Smears of oral cavity** are an excellent medium of diagnosis of this chromosomal disorder by finding sex chromatin bodies, corresponding to the XXY karyotype (see Chap. 4).

Other Causes

Amenorrhea may also occur because of **congenital pituitary insufficiency**. Some of the patients with the classic clinical syndrome of **dwarfism** may show complete absence of maturation in the vaginal smears, but their sex chromatin pattern is normal. In other patients, primary amenorrhea may be due to the **absence of follicle-stimulating hormone (FSH) of the pituitary**. Such patients may appear clinically within normal limits. Their vaginal smears show variable degrees of maturation of the squamous cells; their sex chromatin pattern is normal. Amenorrhea resulting from **congenital absence of the uterus** results in vaginal smears compatible with ovarian function and a normal sex chromatin pattern. These and many other related disorders are caused by single-gene mutations (Adashi and Hennebold, 1999).

Secondary Amenorrhea

In the absence of pregnancy, secondary amenorrhea in a patient of childbearing age with an intact uterus indicates a **temporary or permanent arrest of normal ovarian function**. Except for iatrogenic castration, the value of the vaginal smear in the hormonal evaluation of secondary amenorrhea is far smaller than in primary amenorrhea. **Sex chromatin is present in all patients**, and the effects of various ovarian disorders are **unfaithfully mirrored in the maturation patterns of squamous cells**.

It is important to note that, in the presence of functioning ovaries, a prolonged absence of endometrial turnover may lead to endometrial carcinoma (see Chap. 13).

Disturbances of Ovulation (Polycystic Ovarian Disease, Stein-Leventhal Syndrome)

This group of patients shows a wide spectrum of clinical disorders with the common denominator being the **failure of release of the ovum from the maturing ovarian follicle**. As a result, the estrogen-producing follicles persist, becoming enlarged and cystic. In such patients, the postovulatory part of the cycle is usually absent: **there is no transformation of the follicle into a corpus luteum**. Consequently, the proliferative endometrium does not enter into the secretory phase or the secretory activity is focal or weak. The result of inadequate endometrial desquamation is **endometrial hyperplasia**, or an increase in the absolute amount

of the endometrium, accompanied by various degrees of abnormality of endometrial glands and, in some cases, **endometrial carcinoma** (see Chap. 13). Ovarian stroma may show transformation into luteinized theca cells, which, in extreme cases, may be sufficiently extensive to be mistaken for an ovarian tumor (pseudothecoma of ovary, Koss et al, 1964). The accompanying amenorrhea may be intermittent or permanent and may be accompanied by episodes of heavy uterine bleeding or **metrorrhagia**.

In the group of patients with an ill-defined variant of this group of disorders, the **Stein-Leventhal** syndrome, fibrosis of the ovarian cortex may occur and was thought to be the cause of ovulatory disturbances. Indeed, a wedge resection of the ovaries may restore normal cyclic bleeding in some patients. However, many such cases show no evidence of cortical ovarian fibrosis.

The clinical setting of these disorders is fairly characteristic; periods of amenorrhea usually affect young women in their teens or early 20s. **Obesity, hirsutism, diabetes, and hypertension** are not infrequently observed and may occur either singly or in any combination. There is usually no biochemical evidence of either pituitary or adrenal disorders. The disturbance may be temporary, with a spontaneous return to normal, but more often it persists unless treated. The chief danger lies in the development of endometrial hyperplasia and **endometrial carcinoma**.

P.234

Cytology

In view of the arrest of ovulation, one would expect that the vaginal smears of patients with Stein-Leventhal syndrome would show a sustained high level of estrogenic activity. This has not been our experience, or the experience of Rakoff (1961) or of Bamford et al (1965). The cases are too few and inadequately followed for a conclusive statement but, in general, the vaginal smears are composed of folded and clustered superficial and intermediate cells, thus resembling the postovulatory-type smears (see Chap. 8). Intracytoplasmic glycogenic deposits may occur and such smears may mimic the pattern observed in pregnancy.

Occasionally, however, especially in the presence of endometrial hyperplasia, a high level of estrogenic activity may be observed (see also Chap. 13). If sequential smears are taken over time, there is usually little variation in smear pattern. Pronounced cyclic variations are rarely seen and usually precede an episode of metrorrhagia.

Effects of Castration

The effects of castration, either surgical or radiation-induced, may be conveniently followed by vaginal smears. The effects of **surgical castration** are by no means uniform. In fact, complete atrophy of the squamous epithelium may not occur for several months or even years.

Finkbeiner (unpublished data) who observed numerous surgically castrated patients with breast cancer, noted that in some of them a drop in the level of maturation of squamous epithelium was followed within a few weeks by an improved maturation (Fig. 9-2). This suggests that other sources of ovarian-like hormones, possibly the adrenal cortex, are able to step in to replace the missing ovaries. The effects of **radiation-induced castration** are still more variable and, not infrequently, the cytologic pattern may fail to reach the stage of complete epithelial atrophy. The cytologic evaluation here may be complicated by the effect of radiation on epithelial cells, described in Chapter 18.

Figure 9-2 Diagrammatic representation of the differential cell count technique for hormonal evaluation of vaginal smears. From 200 to 400 cells are counted under high-dry magnification, enumerating the percentage of small parabasal, large parabasal, intermediate, precornified, and cornified cells as diagrammed. The *right-hand* portion of the diagram illustrates the clinical application of this method of endocrine evaluation in the follow-up care of patients with advanced breast cancer. This patient, a 61-year-old woman, who was 8 years postmenopausal, had recurrent inoperable breast cancer with multiple osseous and soft-tissue metastases. The individual bars represent a single day's smear pattern; the confluent bars are consecutive smears. The preoperative vaginal smears show a greater maturation of squamous cells than would ordinarily be expected in a patient of this endocrine status, suggesting that this tumor was growing in a relatively rich hormonal environment. Combined oophorectomy-adrenalectomy was followed by an excellent objective and subjective remission, with measurable regression of disease. The vaginal smear response to this procedure is shown. There was again a slight increase in vaginal smear maturation just before the appearance of recurrent disease, 10 months postoperatively. (Courtesy of Dr. John A. Finkbeiner.)

OTHER DISORDERS WITH HORMONAL EFFECTS

Ovarian Tumors

Certain ovarian tumors, particularly the **granulosa cell tumors and the thecomas**, may produce estrogen-like substances. The resulting clinical disorders resemble those observed in disturbances of ovulation, as discussed above. The vaginal smear patterns are generally uninformative during the childbearing age. However, granulosa cell tumors may occur in all age groups and **the finding of a consistently high estrogenic effect in a prepubertal or postmenopausal woman warrants investigation of the ovaries**. High level of maturation of squamous cells after treatment of this tumor may be suggestive of a recurrence (see Chap. 15).

Ovarian tumors, usually classed as masculinizing (**arrhenoblastomas or Sertoli-Leydig cell tumors, hilar cell tumors, lipoid cell tumors**), are exceedingly rare. Little

P.235

is known about the effect of these tumors on the vaginal smear. Rakoff (1961) reported the finding of an **atrophic smear type** in two patients with **arrhenoblastoma**, and a mixed

population of squamous cells in a child with “**adrenal-like ovarian tumor**” (possibly a variant of granulosa cell tumor) and in a young woman with “lipoid cell tumor.” Rakoff's studies occurred before the current nomenclature of the ovarian tumors was in place and, in the absence of histologic data, the tumors cannot be reclassified.

Precocious Puberty in Girls

In this uncommon disease affecting young girls and caused by a single-gene defect (Adashi and Hennebold, 1999), there is usually the association of **premature periodic vaginal bleeding and hyperplasia of breasts with a disease of the skeleton** (fibrous dysplasia) and **café-au-lait spots on the skin** (**McClure-Albright's syndrome**) (Figs. 9-3 and 9-4). Sequential vaginal smears disclose cyclic variation of the smear pattern, as shown in Figure 9-4A, corresponding to a cyclic function of the ovary.

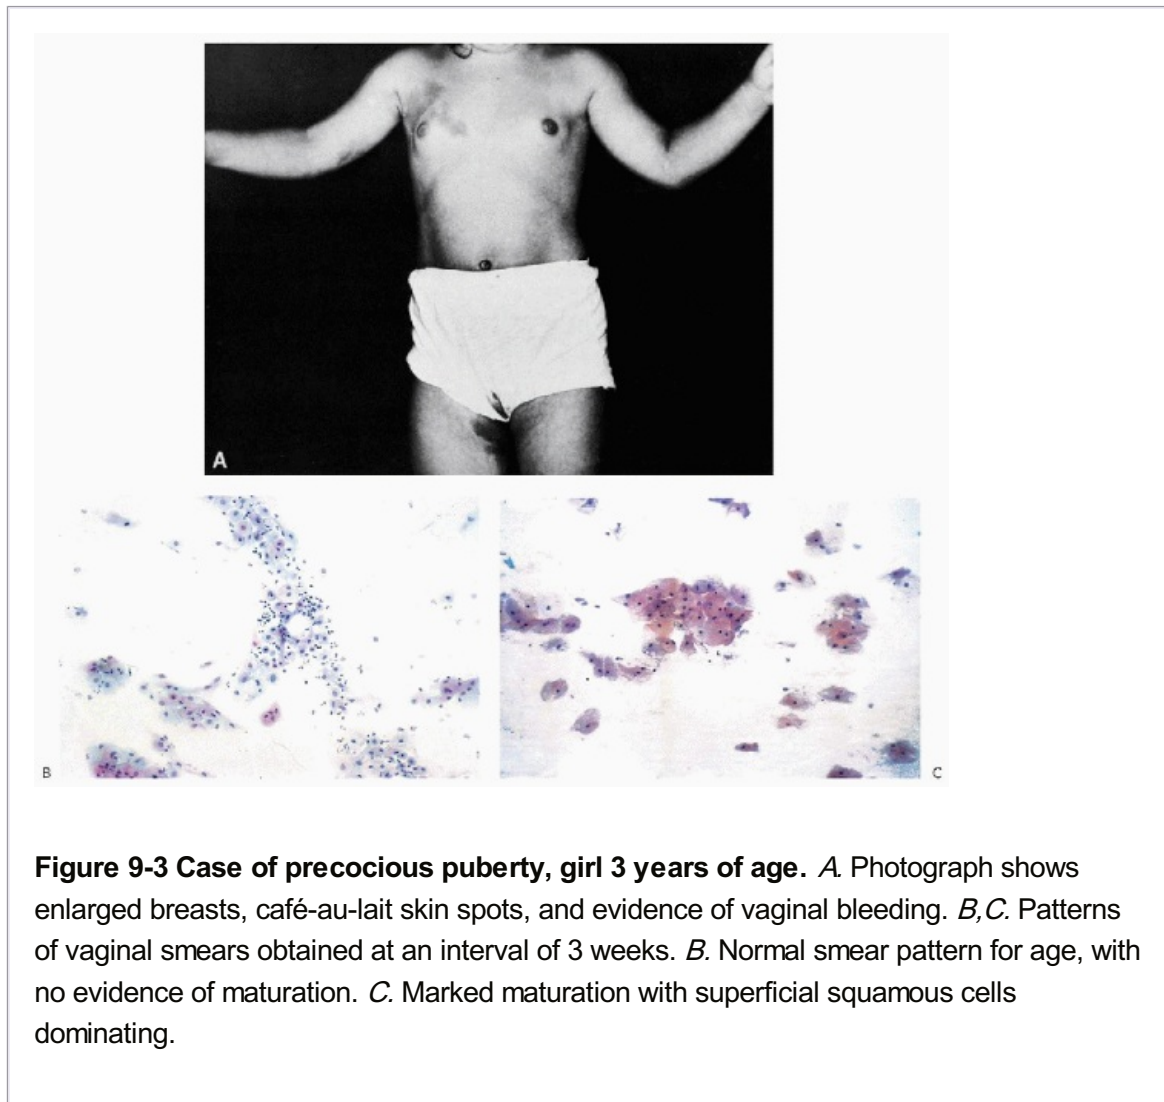

Figure 9-3 Case of precocious puberty, girl 3 years of age. *A.* Photograph shows enlarged breasts, café-au-lait skin spots, and evidence of vaginal bleeding. *B,C.* Patterns of vaginal smears obtained at an interval of 3 weeks. *B.* Normal smear pattern for age, with no evidence of maturation. *C.* Marked maturation with superficial squamous cells dominating.

Endometriosis

Endometriosis may sometimes lead to abnormal uterine bleeding. Although Schmidt and Christiaans (1965) claimed that endometriosis results in elevation of the maturation of squamous cells, when compared with normal for the time of the cycle, it has been our experience that there are no cytologic findings, whether quantitative or qualitative, that would permit the diagnosis of endometriosis in vaginal smears. For further discussion of cytologic findings in endometriosis, see appropriate chapters.

Galactorrhea

During the period of **normal lactation**, the vaginal smear pattern is that of the postpartum type (see Chap. 8). If

P.236

normal lactation continues over a period of many months or years, it is usually accompanied by **amenorrhea** and a marked **atrophy of the squamous epithelium (Chiari-Frommel syndrome)**. Occasionally, **galactorrhea** or milk formation may occur independently of pregnancy, and this may reflect a serious endocrine disorder, such as a **chromophobe adenoma of the pituitary** (see Chap. 29). In such instances, the **smear pattern may show moderate proliferation of the squamous epithelium**, even in the absence of documented estrogen or progesterone activity.

Figure 9-4 Same case as in Figure 9-3. *A*. Diagrammatic representation of sequential vaginal smears. A pattern of cyclic maturation is evident. *B*. Roentgenogram of a lesion affecting the left fibula of this child, which proved to be fibrous dysplasia.

Hepatic Insufficiency

Patterns suggesting excessive levels of estrogens may also be noted in the presence of hepatic insufficiency. This is generally attributed to failure of the damaged liver cells to metabolize estrogens.

EFFECTS OF HORMONAL THERAPY ON THE SQUAMOUS EPITHELIUM

Estrogens

Except during pregnancy, parenteral or oral administration of estrogens and estrogen substitutes produces a **cytologic pattern of complete maturation of squamous**

epithelium. The effect is particularly evident in postmenopausal or prepubertal patients and may result in a striking and radical change of smear pattern, with a preponderance of single flat, superficial cells. Occasionally, very large squamous cells have been observed. Even the **administration of facial or vaginal creams containing estrogens may be reflected in the vaginal smears.** There is, however, **no direct quantitative relationship between the amount of the drug administered and the response of the squamous epithelium.** This relationship varies significantly from patient to patient. Some patients require large doses of estrogens to achieve full maturation of the squamous epithelium; others require very little drug. Once the full maturation of the squamous epithelium has been reached, further increases in the dosage of the drug will not be reflected in further changes in the smear pattern. The use of the vaginal smear as the sole guide in the therapeutic administration of estrogenic substances is probably not warranted.

If estrogen is withdrawn, its effect on the squamous epithelium may linger for some days or weeks but the stimulated **endometrium may break down** with resulting clinical spotting or bleeding (**withdrawal bleeding**). Clusters of endometrial cells may be observed in such smears (Fig. 9-5). The effect of estrogens on smear patterns in various conditions is summarized in Figure 9-6.

P.237

Figure 9-5 Effect of estrogen. Large, mature squamous cells in the cervicovaginal smear of a 70-year-old woman. A cluster of endometrial cells seen in the photograph was shed as the drug was being withdrawn (withdrawal bleeding).

There is considerable controversy about the value of **estrogen therapy used to alleviate the effects of the menopause.** On the one hand, this therapy is beneficial in preventing some of the common symptoms, such as hot flashes, and is perhaps useful in preventing osteoporosis. On the other hand, the drug may contribute to the development of endometrial hyperplasia and carcinoma, although this latter issue is by no means clear-cut (see Chap. 13). Further, the drug may contribute to the development of breast cancer (Clemons and Goss, 2002; Chlebowski et

al, 2003). Still, it is preferable to use estrogens together with progesterone in a form of cyclic therapy to prevent any untoward effects on the endometrium, but the value of this therapy in reference to coronary heart disease has been recently questioned (Manson et al, 2003). Still, the hormonal effects of the combined therapy may be monitored by cytology.

Figure 9-6 Schematic representation of effects of estrogens on patterns of vaginal smears. The effect is most striking in advanced atrophic menopause (*top*) and in early menopause (*center*), and results in full epithelial maturation with formation of squamous superficial cells. There is no effect on the smear pattern in normal pregnancy (*bottom*). (From Wied G. Hormonal evaluation of the patient through cytologic interpretation. *Acta Unio Int Contra Cancrum* 14: 277-285, 1958.)

Other Hormones Influencing the Patterns of Squamous Epithelium

The response to a variety of hormones varies according to the menstrual status of the patient. **During the childbearing age** the administration of **progesterone or of androgens**, such as testosterone, may result in **some degree of suppression of maturation of the squamous epithelium, with intermediate cells** dominating the smear pattern. Intracytoplasmic glycogen deposits may be observed in such cells. The effect of androgens on smear patterns in various

conditions is summarized in Figure 9-7.

In women with postmenopausal atrophy, whether spontaneous or iatrogenic, the administration of a variety of hormones, such as **progesterone, androgens, adrenal cortical steroids, or anterior pituitary hormones**, may bring about some measure of epithelial stimulation in most cases. Thus, cervicovaginal cytology is of a very limited value in assessing the effect of these drugs.

Contraceptive Medication

The cytologic effect of hormones administered for contraceptive purposes varies according to the make-up of the product. The commonly used drugs, composed of a mixture

P.238

of estrogen and progesterone derivatives, may result in **some arrest of maturation of the squamous epithelium**, occasionally suggestive of a degree of epithelial atrophy. The effect of progesterone on endocervical cell morphology is discussed in Chapters 8 and 10.

Figure 9-7 Schematic representation of the effects of parenterally administered androgens on patterns of vaginal smears. In advanced menopause (*top*) about 70% of women will show moderate epithelial maturation, whereas the drug will be without effect in 30% of cases. There is no noticeable drug effect on patterns of early menopause (*center*). During the childbearing age (*bottom*), there may be some arrest of epithelial maturation. (From Wied G. Hormonal evaluation of the patient through cytologic interpretation. Acta Unio Int Contra Cancrum 14:277-285, 1958.)

The **long-term implanted contraceptive hormonal devices** usually contain progestogens (Johannisson, 1990). Valente et al (1998) described the long-term effect of one of these drugs (depot-medroxyprogesterone acetate) on young users, using the maturation value (MV). Many of the users developed amenorrhea, accompanied by **atrophic or postpartum patterns of smears** with significant lowering of the MV, when compared with control patients matched for age. Nothing is known about the hormonal effects of a new class of drugs, such as RU 486, that interfere with implantation of the ovum and thus effectively induce abortions (Baulieu, 1989).

Tamoxifen

This important **estrogen agonist** is now widely used in the treatment and prevention of carcinoma of the breast. Studies by Eells et al (1990), Lahti et al (1994), and by Friedrich et al (1998) pertaining to the impact of the drug on the hormonal pattern of cervicovaginal smears in **postmenopausal women** indicated that these patients have an **increased maturation of the squamous epithelium**. In an elaborate study, Bertolissi et al (1998) studied karyopyknotic index (KI), the maturation index (MI), and the levels of hormone-binding globulin in 64 postmenopausal breast cancer patients receiving tamoxifen. Statistically significant increases in both indices and the globulin were observed in about 80% of the patients after 30 days of therapy and remained stable during the follow-up period of 12 months. This study confirmed that the drug induced an early and persistent estrogenic effect on the squamous epithelium of the lower genital tract. In a number of personally observed cases, the smear patterns were dominated by intermediate squamous cells. Thus, although the drug is an estrogen agonist, **it does not induce atrophy of the squamous epithelium or prevent its maturation. The effect of the drug is similar to that of steroid hormones other than estrogen**, as discussed above. Gill et al (1998) suggested that tamoxifen induces atypical benign changes in squamous cells.

P.239

We have not seen such changes, and the full significance of this observation will require long-term controlled studies. The significance of tamoxifen in the **genesis of endometrial abnormalities and carcinoma** is discussed in Chapter 13. It is not clear whether or not tamoxifen is the cause of **vaginal adenosis**, as described by Genesan et al (1999). For further discussion of vaginal adenosis, see Chapter 14.

TABLE 9-2 THE EFFECT OF DIGITALIS ON MATURATION OF SQUAMOUS EPITHELIUM IN POSTMENOPAUSAL WOMEN

Length of Digitalis *	Maturation of Squamous
-----------------------	------------------------

Number of Patients		Therapy	Epithelium

* As oral digitoxin 0.1-0.2 mg daily.
(Navab A, et al. Estrogen-like activity of digitalis. Its effect on the squamous epithelium of the female genital tract. JAMA 194:30-32, 1965.)

Drugs Other Than Hormones

The **antibiotic**, tetracycline, may be used to treat inflammatory conditions in the vagina. In the course of personal studies on carcinoma in situ of the cervix (see Chap. 11), it became apparent that **tetracycline vaginal suppositories have a marked desquamatory effect on the squamous epithelium** of the female genital tract. Smears from treated patients may contain sheets of desquamated squamous cells that are difficult to evaluate. At least 1 week, preferably longer, should be allowed to elapse after conclusion of treatment before the evaluation of the squamous epithelium is undertaken. It is quite likely that **other antibiotics** and perhaps **intravaginal medication** of any kind may influence patterns of maturation of squamous cells.

Studies by Britch and Azar (1963) and by Navab et al (1965) on the effects of **digitalis** on postmenopausal women revealed that this drug, if administered daily for 2 years or longer, has a marked influence on the maturation of the squamous epithelium. The results are summarized in Table 9-2. The manner in which digitalis, a compound biochemically related to steroids, affects the squamous epithelium of the vagina is unclear. **Gynecomastia in men**, also observed after digitalis therapy, may represent an allied phenomenon.

Benign Disorders of the Uterine Cervix and Vagina

NONINFLAMMATORY AND REACTIVE PROCESSES

In this chapter, a number of benign epithelial cytologic abnormalities is described. The knowledge of these abnormalities is essential in the practice of cytopathology because some of these changes must be differentiated from malignant processes. The abnormalities will be presented according to the epithelium of origin but in practice may be found side by side in the same cytologic preparation.

SQUAMOUS EPITHELIUM

Basal Cell Hyperplasia

This is a frequent finding in the biopsies of the cervix, as it is in other organs, such as the bronchus. On histologic examination, there is an **increase in the number of layers of small basal cells**. Consequently, the basal cells form one-fourth to one-third of the thickness of the squamous epithelium (see Fig. 6-11). However, there are **no nuclear abnormalities** and the maturation of the epithelium proceeds

P.242

normally above the enlarged basal zone; hence, basal hyperplasia of squamous epithelium **cannot be detected in smears** unless there is a total loss of superficial cell layers or if the sample is obtained by energetic brushing. The etiology of the process is unknown but there is no evidence that it is related to cancer.

Leukoplakia

Leukoplakia (from Greek, *leukos* = white) is a clinical term describing a **white patchy discoloration of the squamous epithelium**. It is more common on the surface of the cervix than in the vagina. In most cases, it is a benign lesion caused by **abnormal keratinization of the mucosal surface**. It must be emphasized, however, that **keratinizing precancerous lesions of the uterine cervix and occasionally, keratinizing invasive carcinoma, may appear as clinical leukoplakia** (see Chap. 11).

Histology

In benign leukoplakia, the surface of the epithelium is covered by an **eosinophilic layer of keratin of variable thickness**. The keratinized layer is composed of anucleated cells, akin to those observed on the surface of the epidermis (Fig. 10-1A). The lesion may result from chronic trauma, prolapse of the uterus, pressure of a pessary, or previous cauterization of the cervix.

Cytology

Anucleated squamous cells (**squames**), of characteristic **pale yellow color** in Papanicolaou stain, are shed from the surface of the keratinized squamous epithelium (Fig. 10-1B). All stages of transition between mature nucleated squamous cells and the anucleated variety may be observed: There is a gradual change in the color of the cytoplasm from pink to yellow and the gradual disappearance of the nucleus. In the fully keratinized squames, **shadows of pre-existing nuclei can be observed**. Occasionally, brown cytoplasmic granules, akin to those seen in the normal superficial squamous cells, may be noted. The actual **frequency** of anucleated squamous cells in cervicovaginal smears is low, estimated by Kern (1991) to be about 0.5%. In my opinion, the presence of anucleated squamous cells **should be noted in the report** because of the remote possibility that these cells may have originated from the surface of a squamous cancer, masquerading as leukoplakia. Such patients deserve a closer clinical look, although nearly all the lesions are benign. **In squamous carcinomas with features of leukoplakia, anucleated squamous cells are usually accompanied by cells with abnormal, hyperchromatic nuclei that allow an accurate diagnosis**, as discussed in Chapter 11.

Figure 10-1 Leukoplakia of uterine cervix. *A.* Biopsy showing a layer of keratin on the surface. *B.* Cervical smear from the same case. The yellow or yellow-orange superficial squamous cells are either anucleated (anucleated squames) or show residual traces of nuclei.

Parakeratosis (Pseudoparakeratosis) of Squamous Epithelium

Histology

Occasionally, the surface of an otherwise normal squamous epithelium of the uterine cervix is lined by a few layers of very small nucleated squamous cells, instead of the usual large, mature squamous cells. This disorder is somewhat similar to the abnormalities occurring on the surface of the epidermis of the skin (for example, in psoriasis), which are referred to as **parakeratosis**. Therefore, this abnormality of the cervix epithelium was named **pseudoparakeratosis**.

Cytology

In cervical smears, large sheets of **irregularly-shaped, small squamous cells**, about 10 μm in diameter, with basophilic or eosinophilic cytoplasm, may be observed (Fig. 10-2A). The nuclei are spherical, of even sizes, often somewhat eccentric and usually pyknotic (Fig. 10-2B). The cause or the exact frequency of this **benign** abnormality is unknown. Voytek et al (1996)

observed similar small cells in benign lesions but also in the presence of low- and high-grade squamous neoplastic lesions of the cervix. It is not certain whether this association is incidental. Still, the recognition of the pseudoparakeratotic cells as benign is sometimes very difficult because of their nuclear features. In case of doubt, colposcopy and biopsies of the cervix should be recommended. Frable (1994) included such cells among the **litigation**

P.243

cells that are difficult to classify and may be the subject of a dispute as to their exact significance.

Figure 10-2 Pseudoparakeratosis or parakeratosis. *A.* The cervical smear at survey magnification shows large sheets of very small squamous cells. *B.* At higher magnification, the spherical or slightly irregular cells have uniform, dark nuclei.

Somewhat similar cells were observed by Meisels and Fortin (1976) in **human papillomavirus (HPV) infection** and were named **dyskeratocytes**. Dyskeratocytes, as described and illustrated, are small **elongated, spindly cells** forming sheets with similar nuclear characteristics to pseudoparakeratotic cells described above. Meisels et al (1976) observed HPV virions in electron microscopy of dyskeratocytes. However, in pseudoparakeratosis, the underlying epithelium does not show any changes of papillomavirus infection and, therefore, the two entities may be similar but are possibly of different etiologies. (See Chap. 11 for further discussion of cytologic manifestations of human papillomavirus infection.)

ENDOCERVICAL EPITHELIUM

Basal Cell Hyperplasia

Histology

Proliferation of the small, basal endocervical cells, akin to the basal hyperplasia of squamous epithelium, may result from chronic inflammation or it may occur spontaneously. In tissue sections, **several layers of small, round cells are found beneath the columnar endocervical cells** (see Fig. 6-12).

Cytology

Basal cell hyperplasia is **rarely seen in cervical scrape smears**. However, with the use of **cervical brush instruments**, particularly after a vigorous brushing, basal cell hyperplasia may be seen from time to time in the form of **flat clusters of small, spherical or polygonal cells**,

measuring about 10 μm in diameter. The cells have scanty cytoplasm and relatively large, **dense but regular nuclei, about 8 μm in diameter**. The nuclei vary somewhat in size and shape and **may show mitotic activity**. The recognition of the basal endocervical cells is easier if well-differentiated columnar cells are attached to the periphery of such clusters (Fig. 10-3). The role of basal cell hyperplasia as a **step in squamous metaplasia** of the endocervical epithelium is discussed below.

The significance of basal cell hyperplasia of endocervical epithelium is in the **similarity of these small benign cells to small cancer cells**. The benign cells occur in flat clusters that are rarely dispersed. Also, the basal cells lack the nuclear features characteristic of cancer cells, described and discussed in Chapter 11. Errors of interpretation of such small cells may be twofold: **benign basal cells may be mistaken for cancer cells but, more often, the small cancer cells are mistaken for benign cells, sometimes with disastrous consequences for the patient**.

Squamous Metaplasia

Squamous metaplasia is a **replacement of normal endocervical epithelium by squamous epithelium** of varying degrees of maturity (see Fig. 6-12). This is a very frequent event that may be confined to a small area of the endocervix

P.244

or may be very extensive and involve the **surface epithelium and the glands**. Squamous metaplasia is a **normal, physiological event** during maturation of the female genital tract, notably in the epithelium of the transformation zone, as discussed in Chapter 8.

Figure 10-3 Basal cell hyperplasia of endocervix. A cluster of relatively small polygonal cells attached to well-differentiated endocervical cells.

Pathogenesis

Electron microscopic studies, notably by Bonilla-Musoles and Barbera (1970) and by Philipp

(1975), documented that the small **basal or reserve cells** of the endocervical epithelium have the dual potential of differentiating either into mucus-producing normal endocervical cells or into squamous cells, a view confirmed by Tsutsumi et al (1993). It is likely that **hormones**, notably estrogens, play a role in the origin of squamous metaplasia. However, because squamous metaplasia is often observed in biopsy material from cervixes showing chronic inflammation, it has also been linked to **inflammatory processes**. Squamous metaplasia is also observed in the presence of intrauterine contraceptive devices and, therefore, may be a **reaction to mechanical pressure**. The precise mechanisms leading to squamous metaplasia must still be elucidated. There may be some **analogy between squamous metaplasia and the events occurring in the formation of the epidermis**, as proposed by Sun et al (see Chap. 2). Sun documented that the transformation of a simple cuboidal epithelium into mature epidermis of the skin is accompanied by a sequential activation of keratin genes of ever higher molecular weights (see Fig. 2-25). Still, keratin polypeptides in metaplastic epithelium appear to be unique and differ from cytokeratins normally present in the squamous epithelium of the cervix and those found in the endocervical epithelium (Gigi-Leitner et al, 1986).

Figure 10-4 Squamous metaplasia of endocervix. *A.* A focus of squamous metaplasia undermining the endocervical glandular epithelium. *B.* Various stages of squamous metaplasia of the endocervix ranging from mature to immature manifestations of this process. *C.* A cluster of cells from a cervicovaginal smear corresponding to *B* and showing cohesive sheets of metaplastic cells. *D.* Sheets of metaplastic squamous cells showing the characteristic irregular configuration of the cytoplasm.

The metaplastic epithelium occurring within the area of the **transformation zone (squamocolumnar junction)** is commonly **involved in initial neoplastic events** affecting the uterine cervix, as discussed in Chapter 11.

Histology

The earliest stages of squamous metaplasia can be identified as a focus of multiplication of the basal cells of the endocervical epithelium. As these small cells grow towards the surface and

become larger, their **cytoplasm becomes eosinophilic and homogeneous** (Fig. 10-4A). The glandular epithelium may remain on the surface while the underlying squamous epithelium forms increasingly mature cells. In most cases, however, the glandular surface epithelium is cast off and the endocervical epithelium is replaced by squamous

P.245

epithelium that may be either **mature, resembling the squamous epithelium of the vagina**, or **immature**, composed of **smaller squamous cells of intermediate or parabasal type** (Fig. 10-4B). The term *immature*, as used here, should not be confused with a malignant process. Various stages of transition between normal endocervical epithelium and mature metaplastic squamous epithelium may be observed. By special stains, **mucus may nearly always be demonstrated** in the cytoplasm of the metaplastic cells, indicating close relationship to the endocervical epithelium. Squamous metaplasia may replace the endocervical mucosa lining the **endocervical canal** or **endocervical glands**. Squamous metaplasia of endocervical glands may be discrete and focal, or diffuse. In extreme cases, one or several glands may be filled with squamous epithelium. If the metaplastic squamous epithelium is **immature, the finding may mimic a neoplastic process**, as discussed below under atypical metaplasia.

Cytology

Only immature squamous metaplasia can be identified in cytologic material because cells derived from mature metaplasia cannot be distinguished from normal squamous cells. Squamous metaplasia of the endocervical mucosa can be diagnosed **with certainty in cervical smears** if flat sheets of **polygonal parabasal squamous cells with basophilic or eosinophilic cytoplasm** are **contiguous with columnar endocervical cells** (Fig. 10-4C). Within the sheets, the metaplastic squamous cells usually form **clearly visible cell borders**. One surface of the sheets is often **flattened**, corresponding to the surface of the metaplastic epithelium. Occasionally, the clusters of metaplastic cells are **loosely structured** and are composed of **angulated squamous cells** (Fig. 10-4D). On close inspection, the distinct **flattening of the surface** of the cluster is evident and sometimes there are transitions toward well-formed, mucus-producing columnar endocervical cells.

The **cytoplasm** of the metaplastic cells is either **basophilic or eosinophilic** and may show **fine vacuoles** in which **mucus** can be demonstrated by special stain. Occasionally, the vacuoles can be large and may be **infiltrated with polymorphonuclear leukocytes**. The **nuclei** of the metaplastic cells are spherical, measuring on the average 8 μm in diameter, but may be larger. Within the nuclei, small **chromocenters** and **occasionally tiny nucleoli** may be observed. Rarely, **small spindly keratinized cells** with slender pyknotic nuclei may originate from the surface of squamous metaplastic epithelium.

Unfortunately, **metaplastic cells in their classical configuration in sheets are not always present in cell preparations, particularly those collected in a liquid medium and subsequently dispersed**. In such preparations, the **parabasal metaplastic squamous cells occur singly** and are usually characterized by **irregular, polygonal configuration with cytoplasmic processes, or spikes**, as commonly observed in parabasal cells removed from their epithelial setting. The **cytoplasmic processes are an artifact** occurring during smear preparation by **extensions of the cytoplasm at points of desmosomal junctions** with adjacent cells. As the cells are being separated during smear preparation, the solid desmosomes resist rupture better than the elastic cytoplasm, which, as a consequence of

mechanical stretching, becomes elongated at points of junction. Occasionally, one surface of these cells is flat, corresponding to the lining of the endocervical canal (see Fig. 10-8A).

As has been discussed in Chapter 8, the mere **presence of parabasal squamous cells in a cervicovaginal smear is not diagnostic of metaplasia**. Such cells may originate from the squamous epithelium of the vagina or the cervix under a variety of circumstances unrelated to metaplasia. The term **metaplastic cells** that has been suggested for parabasal cells, while picturesque, is not always scientifically sound.

Several attempts have been made to distinguish metaplastic cells from parabasal cells derived from native squamous epithelium by identification of keratins of various molecular weights. Thus, keratins 15, 16 and, occasionally, keratin 6 were observed in endocervical reserve cells and in squamous metaplasia (Smedts et al, 1993) whereas positive stain for keratin 17 was found useful in the differentiation of metaplastic cells from normal parabasal cells (Martens et al, 1999).

Still, **if angulated parabasal cells are trapped in the endocervical mucus or if the sample has been removed directly from the transformation zone or the endocervical canal by an instrument, such cells may be considered as adequate evidence that the smear is representative of the endocervical epithelium undergoing squamous metaplasia**. The information on the value of such findings in liquid preparations as evidence of smear adequacy is not available. This issue is important in ensuring the adequacy of cervical smears, discussed in Chapter 8.

Atypical Squamous Metaplasia

Occasionally, the component cells of squamous metaplasia in tissue and smears show slight to severe abnormalities. The **slight changes are cell and nuclear enlargement or binucleation confined to a few cells within the cluster** (Fig. 10-5A). Although, in my experience, slight abnormalities of metaplastic cells are usually of no consequence to the patient and the biopsies in such cases disclose minimally atypical metaplasia, more severe changes, described below, often require further investigation of the patient.

More **severe changes** in metaplastic cells include **significant cellular and nuclear enlargement, variability in nuclear sizes, coarse granulation of chromatin and the presence of prominent nucleoli** (Fig. 10-5B-D). Some of these changes **may resemble “repair,”** discussed below. Because the precise identification of such changes is difficult, their classification as “metaplastic” or “endocervical” may depend on the preference of the observer. No doubt some of these abnormalities could be classified as **atypical squamous or endocervical cells of unknown significance (ASCUS or AGUS)**, which will be discussed in detail in Chapter 11. On further investigation, many such patients

P.246

are subsequently shown to harbor precancerous lesions or even cancer **of either squamous or endocervical type**. Therefore, **patients with marked nuclear changes** (Fig. 10-5B-D) **should have the benefit of a close, careful follow-up, including colposcopy and biopsies of cervix**, particularly if, in addition to cell clusters, single abnormal cells are present in the smear. The role of testing for human papillomavirus in such cases is discussed in Chapter 11.

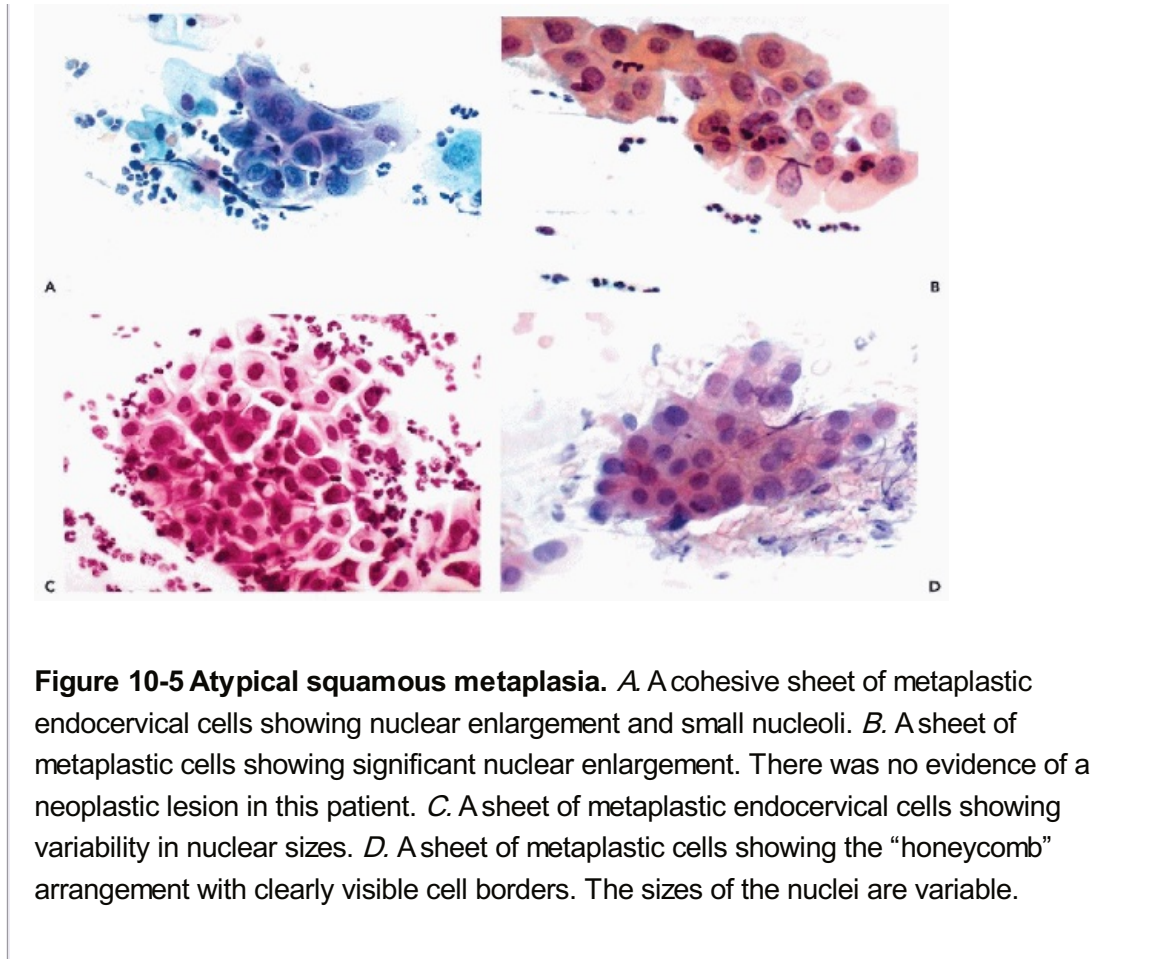

Figure 10-5 Atypical squamous metaplasia. *A.* A cohesive sheet of metaplastic endocervical cells showing nuclear enlargement and small nucleoli. *B.* A sheet of metaplastic cells showing significant nuclear enlargement. There was no evidence of a neoplastic lesion in this patient. *C.* A sheet of metaplastic endocervical cells showing variability in nuclear sizes. *D.* A sheet of metaplastic cells showing the “honeycomb” arrangement with clearly visible cell borders. The sizes of the nuclei are variable.

Tubal and Tubo-Endometrioid Metaplasia

Besides common squamous metaplasia, the endocervical epithelium occasionally shows **features of tubal or endometrial epithelium**, sometimes side by side. The condition has been labeled **metaplasia**, although in all probability, it represents a common variant of normal endocervical epithelium. As noted in Chapter 8 and described in detail by Babkowski et al (1996), **ciliated endocervical cells are invariably present in the upper, proximal reaches of the normal endocervical canal.**

Histology

In 1990, Suh and Silverberg described tubal metaplasia as a replacement of the normal epithelium, lining the endocervical surface and glands, by **epithelium of tubal type**, composed of **columnar ciliated cells, clear secretory cells, and intercalated cells** (Fig. 10-6A). The secretory cells may show apocrine **snouts**, or small cytoplasmic projections, on their surfaces. The variant is common, as it was found in 31% of surgical specimens by Jonasson et al (1992). Some of the endocervical glands may also show the features of **endometrial epithelium**, occasionally accompanied by **endometrial stroma**, and thus suggestive of **endometriosis** (Oliva et al, 1995). The tubal or endometrial lining may form papillary projections and show cystic dilatation. All these features confer on the endocervical glands an unusual aspect that may vaguely resemble **precursor lesions of endocervical adenocarcinoma**, discussed in Chapter 12. However, the **cells lining the endocervical glands usually do not show any significant nuclear abnormalities** and are, therefore, consistent with benign lesions. However, personal experience shows that in some of these lesions, **the ciliated epithelium and adjacent endocervical glands may show marked abnormalities in the form of**

accumulation of small, highly abnormal cells with irregular, hyperchromatic nuclei, strongly suggestive of a small cell carcinoma. This observation received strong support from work by Schlesinger and Silverberg (1999) who described several

P.247

cases of endocervical carcinoma in situ of tubal type and stressed that the mere presence of ciliated epithelium does not guarantee that the lesion is benign.

Figure 10-6 Tubal metaplasia. *A.* Biopsy of endocervix showing glands with ciliated surface and minor variability in nuclear sizes. *B.* Ciliated endocervical cells with somewhat hyperchromatic nuclei of even sizes. *C.* A sheet of endocervical cells from the upper reaches of the endocervical canal showing dark, somewhat enlarged nuclei of even sizes.

Cytology of Tubal Metaplasia

With the widespread use of rigorous endocervical brushing techniques the presence of ciliated endocervical cells has become much more common in cervical smears than with the use of cervical scrapers. Thus “tubal metaplasia” became a recognized cytologic entity. In brush smears in some cases of tubal metaplasia, one can observe sheets of essentially normal ciliated endocervical cells with enlarged hyperchromatic nuclei (Fig. 10-6B,C). In some such cases, the nuclear abnormalities may be significant and the cells may be classified as **atypical glandular cells of unknown significance (AGUS)**, requiring further investigation. Ducatman et al (1993) also claimed that one could recognize in smears the “peg cells,” characterized by “dark and granular cytoplasm and elongated nuclei.” We have not been able to identify such cells with certainty.

Cytologic Abnormalities in Tubal Metaplasia

Novotny et al (1992) claimed that tubal metaplasia may shed **abnormal cells** that can be **mistaken for cells derived from precursor lesions of endocervical adenocarcinoma.** These authors provided an elaborate table, listing the cytologic features of both types of lesions. This has not been my experience. As mentioned above, in several cases seen in

consultation in which smears contained **ciliated cells accompanied by small abnormal or suspicious cells, the corresponding biopsy material disclosed marked abnormalities of endocervical glands and adjacent endocervical epithelium, consistent with a malignant process.** Within the neoplastic epithelium, ciliated cells were occasionally present. These observations confirm that **cytologic abnormalities always have their counterpart in corresponding histologic material and are in keeping with the concept of carcinomas with ciliated cells, perhaps developing in tubal metaplasia,** as described by Schlesinger and Silverberg (1999). For further discussion of precancerous lesions of the endocervical epithelium, see Chapter 12.

Endometriosis

It has been mentioned above that Oliva et al (1995) observed the presence of endometrial stromal cells in areas of endometrioid metaplasia of the endocervix, consistent with the diagnosis of endometriosis. Similar observations were reported by Yeh et al (1993). No specific histologic or cytologic abnormalities were attributed by these authors to the histologic findings. However, Mulvany and Surtees (1999) reported that the **cervical brush smears in 7 of 10 cases of endometriosis located in the uterine cervix or vagina contained cells interpreted as consistent with endocervical adenocarcinoma, either invasive or in situ.**

The cytologic

P.248

abnormalities consisted of **nuclear hyperchromasia, large cohesive cell clusters, and the presence of mitotic activity and of necrotic cells, described as "apoptosis."** Similar observations were reported by Hanau et al (1997). The histologic findings in these cases disclosed various degrees of atypia in the glands which, in two cases, was "severe." Although Mulvany and Surtees did not classify the abnormalities as malignant, it is well known that endometrioid carcinomas may originate in the endometriotic glands (Koss, 1963; Brooks and Wheeler, 1977; Mostoufizadeh and Scully, 1980). These abnormalities must be considered in the differential diagnosis of endocervical adenocarcinoma.

Lesions Erroneously Classified as Metaplasia

There are few, if any, fields of microscopy that are as difficult to interpret as cervicovaginal cytopathology. The difficulty is compounded by the facts that many of the precancerous lesions of the uterine cervix have an unpredictable behavior and may require many years of follow-up until their true nature becomes evident, as discussed in Chapter 11. The interpretation of the cytologic material and of histologic patterns in **biopsy material** may be equally difficult and the separation of the **atypical metaplastic processes from true neoplasia may depend on the judgment, training, and experience of the observer.** Some investigators have suggested that human **papillomavirus typing** may help in the final classification of such difficult lesions (Crum et al, 1997) but this expensive technique is not always available and not necessarily reliable. It is, therefore, not surprising that under the **term of "metaplasia," several entities have been described in recent years that in the judgment of this writer are an erroneous and misleading misclassification of lesions that belong to the spectrum of precancerous lesions of the uterine cervix.**

Trivijitslip et al (1998) described a **papillary immature metaplasia (PIM)**, a form of somewhat atypical metaplasia with formation of papillary folds. This abnormality was thought to represent an **immature form of condyloma of the uterine cervix epithelium** and was attributed by Mosher to infection with nononcogenic papillomaviruses types 6 and 11. Still, in a further study

of PIM by Trivijitslip and Mosher (1998), **three of nine patients with PIM harbored a high-grade squamous intraepithelial lesion**. Thus, PIM should be included in the spectrum of precancerous events in the uterine cervix.

A particularly **dangerous concept** has been introduced into cervical cytology by Dressel and Wilbur (1992) under the term **atypical immature squamous metaplastic cells**. **Atypical metaplastic cells are small cancer cells that have some superficial similarity to metaplastic cells but differ markedly by the configuration of nuclei**. Such cells are described and discussed in Chapter 11. In an elaborate study, Geng et al (1999) confirmed the neoplastic nature of "atypical immature metaplasia." In 12 of 15 patients in whom the presence of human papillomavirus DNA was documented by polymerase chain reaction, a concurrent or subsequent diagnosis of a high-grade squamous epithelial lesion was established on biopsies. Park et al (1999) concluded that observer agreement in the differential diagnosis of this lesion from a high-grade neoplastic lesion was poor and not assisted by HPV typing.

Another misleading concept has been introduced by Egan and Russel (1997) under the name of **transitional (urothelial) cell metaplasia of the uterine cervix**. The entity was also described by Weir et al (1997) but was strenuously rejected by Koss (1998). In my judgment, many of the lesions described represent **intraepithelial neoplastic lesions of the uterine cervix undergoing atrophy** and occurring mainly in postmenopausal women. Harnden et al (1999) admitted that the so-called transitional metaplasia lacks the cardinal features of the urothelium. In many such cases, the cytologic and biopsy findings suggested a high-grade squamous intraepithelial lesion (HGSIL).

The entities inappropriately classified as **metaplasia** are discussed again in Chapter 11 together with other precancerous lesions of the cervix.

Microglandular Hyperplasia of Endocervical Glands

In 1967, Taylor et al reported that, in biopsies of patients receiving contraceptive hormones, a **marked proliferation of small endocervical glands** may be observed. The lesion may be polypoid and imitate an endocervical polyp or, in rare cases, adenocarcinoma of the cervix or endometrium (Young and Scully, 1989). Numerous other reports were published subsequent to Taylor's paper, generally attributing this lesion to contraceptive medication containing progesterone (recent summary in Candy and Abell, 2001). There is no doubt, however, that such lesions **may also be observed in the absence of contraceptive medication, in pregnant and postmenopausal women**, and, in about one-fourth of all cases, without an obvious cause at all.

Histology and Cytology

In tissue sections, microglandular hyperplasia consists of a grouping of well-formed endocervical glands of markedly variable sizes. The glands are lined by normal endocervical cells. The proliferation of smaller glands may deceptively suggest an invasion of the stroma and thus adenocarcinoma (Fig. 10-7A). Unusual histologic presentation of these lesions may include areas of solid growth and mucus-containing signet ring cells (Leslie and Silverberg, 1984; Young and Scully, 1989). In some such cases, the differentiation from endocervical or endometrial adenocarcinoma may cause problems. Clinical history and absence of mitotic activity and nuclear abnormalities are usually sufficient to reach the correct diagnostic conclusion.

On the other hand, some well-differentiated carcinomas may sometimes mimic microglandular

hyperplasia. Nuclear abnormalities and mitotic activity are present in such lesions (Young and Scully, 1992). It has been suggested by Daniele et al (1993) and Alvarez-Santin et al (1999) that microglandular hyperplasia can be recognized in cervical brush smears by the presence of 2- and 3-dimensional fenestrated clusters of endocervical cells, some forming small, gland-like structures

P.249

(Fig. 10-7B). In order to secure such clusters, a very energetic brushing of the endocervix is required. **In our experience, there are no specific cytologic abnormalities that would allow a reproducible recognition of microglandular hyperplasia.** Some of the findings described are most likely artifacts caused by endocervical brushings (see below). However, some observers reported marked cytologic abnormalities associated with microglandular hyperplasia (Valente et al, 1994; Selvaggi and Haefner, 1997; Selvaggi, 2000). It is our judgment that, in such cases, the microglandular hyperplasia is an incidental biopsy finding. There is excellent evidence that the presence of **microglandular hyperplasia does not rule out the presence of precancerous intraepithelial lesions** of the cervix, as first pointed out by Nichols and Fidler (1971), or, for that matter, one of the rare cervical or endometrial **adenocarcinomas mimicking microglandular hyperplasia** (Young and Scully, 1992). Thus, the presence of atypical cells in smears calls for a careful investigation of the uterine cervix by methods discussed in Chapters 11 and 12, regardless whether or not microglandular hyperplasia is present.

Figure 10-7 Microglandular hyperplasia. *A.* Section of endocervix showing numerous glands of uneven sizes and configuration, separated by fibrous stroma and lined by cuboidal cells of even sizes. *B.* A large complex fragment of endocervical epithelium in a brush specimen, conceivably reflecting microglandular hyperplasia.

Other Benign Abnormalities of Endocervical Glands

Tunnel clusters is an arrangement of endocervical glands forming small tubules or “tunnels” (Fluhmann, 1961A). A cystic form of this abnormality has been described (Segal and Hart, 1990).

Mesonephric hyperplasia is a proliferation of the remnants of Gartner (mesonephric) ducts usually located within the smooth muscle of the cervix (Ferry and Scully, 1990; Jones and Andrews, 1993).

Endocervicosis is a proliferation of histologically normal endocervical glands in an abnormal

location, such as the outer rim of the uterine cervix or the urinary bladder (Young and Clement, 2000).

These lesions may be confused with endocervical adenocarcinoma in tissue sections. There is no systematic study of the **cytologic presentation** of these benign lesions. Anecdotal evidence suggests that there are no specific cytologic abnormalities that would allow their recognition. The cytologic presentation of Gartner (mesonephric) duct carcinoma is described in Chapter 12.

ABNORMALITIES OF THE TRANSFORMATION ZONE. EVERSION OR ECTROPION ("EROSION") OF THE CERVIX

As discussed in Chapter 8, the squamous and endocervical types of epithelium usually meet within the **squamocolumnar junction or the transformation zone** of the uterine cervix. In some young women, the two epithelia meet on the surface of the vaginal portio of the cervix, outside of the external os. As a consequence, a **sharply circumscribed red patch appears on the vaginal portio of the cervix**, adjacent to the external os. The patch is lined by the delicate **endocervical glandular epithelium**, which is transparent. The visible vessels of the cervical stroma give the area the **red appearance** on visual inspection. Because to the naked eye the patch may mimic an ulcer, the **faulty clinical term of erosion** has been applied to the lesion. The correct term is **eversion or ectropion** (from Greek: *ek* = out, *trope* = a turning). The ectropion may occupy a small segment of the visible cervix or surround the external os (**circumoral erosion**). The importance of the ectropion is largely **clinical**, inasmuch as the red patch must be **differentiated from true ulceration of the cervix due to inflammation or to cancer**.

Histology and Cytology

The patch is lined by typical endocervical epithelium, sometimes forming papillary folds, containing a normal, occasionally hyperemic stroma (Fig. 10-8A). It is not uncommon to find a few normal endocervical glands in the area

P.250

of the ectropion. Direct cervical smears contain only **fragments of benign endocervical tissue and single columnar endocervical cells** (Fig. 10-8B). Because the delicate epithelium lining the area is readily damaged during the process of obtaining smears, fresh blood is often present in the cytologic specimen. If a portion or all of the everted endocervical mucosa has undergone squamous metaplasia, squamous cells of varying degrees of maturity will appear in smears. The cytologic picture is vastly different from inflammatory or neoplastic lesions that may also occur in this part of the cervix, as described below and in Chapter 11. The eversion requires no treatment because, with the passage of time, it will undergo squamous metaplasia.

Figure 10-8 Eversion of endocervical mucosa. *A.* Histologic section showing the surface of the transformation zone lined by endocervical epithelium. Foci of squamous metaplasia are present. *B.* Sheet of normal endocervical cells characteristic of eversion in cervical smears.

REPAIR (FLORID SQUAMOUS METAPLASIA)

The term **repair** has been introduced into the field of gynecologic cytology by Bibbo et al (1971) and by Patten (1978). These authors described atypical cells of endocervical and squamous origin with a number of abnormal cytoplasmic and nuclear features in patients with recent past history of radiotherapy to the uterine cervix, recent hysterectomy, other clinical procedures, such as cautery or biopsy, past history of severe cervicitis (Bibbo et al, 1971), and “partial or complete destruction (of the epithelium) by infection and inflammation” (Patten, 1978). Thus, this is a very heterogeneous group of patients wherein many different factors may account for the cellular abnormalities. Most important, perhaps, histologic evidence of true repair of a damaged epithelium (i.e., epithelial regrowth over a defect) has not been provided by Bibbo and to a very limited extent by Patten.

The **concept of repair** is valid but only under well-defined circumstances, for example, after a conization of the uterine cervix or other documented form of epithelial injury. In the histologic material, **tongues of poorly formed, young epithelial cells bridging the defect caused by prior surgery may be observed** (Fig. 10-9A). The mechanisms of “repair” or healing of a wounded epithelium are extremely complex (Singer and Clark, 1999) and have not been studied in the uterine cervix but probably resemble those in the skin.

Cytology

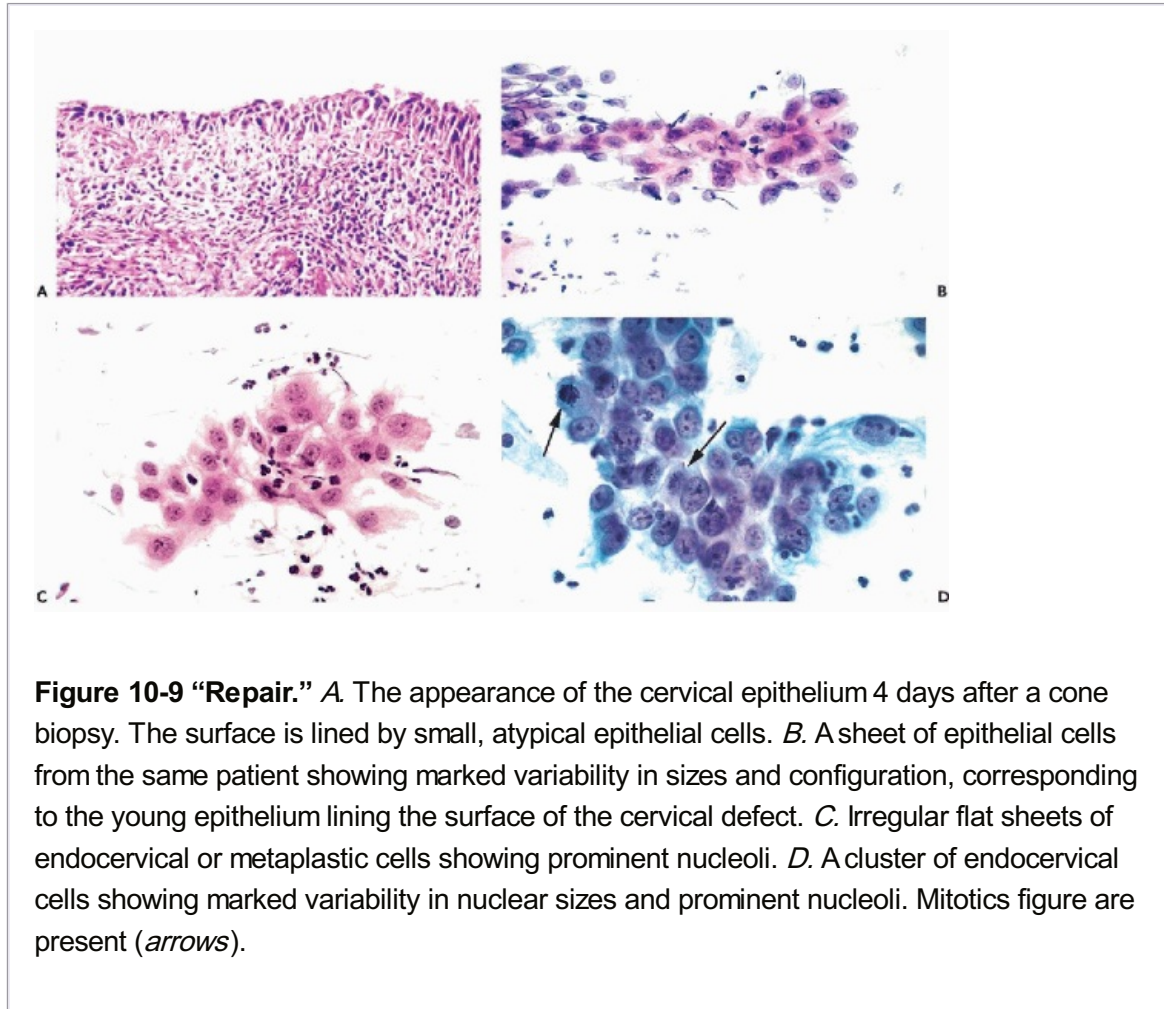

A smear obtained approximately 1 week after a procedure damaging the cervical epithelium may show some rather **characteristic cytologic features**. The smears show **flat sheets, composed of tightly fitting cells, generally resembling metaplastic cells** (Fig. 10-9B,C). The cells may **vary in size** and their cytoplasm may be vacuolated and infiltrated with polymorphonuclear leukocytes. Occasionally, the cells may show **bizarre, sometimes elongated configuration**. The **nuclei** of these cells also **vary in size, may show some degree of hyperchromasia, and, most importantly, contain one or more clearly visible nucleoli of variable sizes. Mitotic figures can be observed** (Fig. 10-9D). There are usually **few, if any, single cells** with similar characteristics. The background of the smear usually shows a great deal of fresh blood and inflammation.

The manifestations of repair may be particularly **difficult to interpret in smears of postmenopausal women with epithelial atrophy**. The nuclei of the epithelial cells are enlarged, of uneven sizes, and hyperchromatic, mimicking malignant lesions. Because the thin epithelial lining offers little protection, bundles of spindly cells representing cervical stroma, may be present. We observed such cells after cervical biopsies, conization, or energetic curettage. “Repair” reaction may occur **after surgical procedures**, as illustrated above, **as a reaction to chronic inflammatory events** or in the presence of a **foreign body or object in the endocervical canal**. For example, **intrauterine contraceptive devices** or **endocervical**

polyps may be the cause of such abnormalities (see below). There remain, however, a number of patients in whom similar cell abnormalities may be observed in smears **in the absence of any known events that could account for the “repair.”** It is likely that, in such patients, the cell abnormalities represent an **exuberant**

P.251

or florid squamous metaplasia of the endocervical epithelium.

The cytologic changes attributed to repair are similar to those occurring in inflammatory changes in the endocervical cells, described further on in this chapter, or in atypical squamous metaplasia, described above. The conspicuous atypia, such as shown in Figure 10-9D, **may reflect a neoplastic lesion, such as a high-grade squamous epithelial lesion or an endocervical adenocarcinoma. In such cases, however, the cell clusters are usually accompanied by single cells with similar morphologic features** (see Chaps. 11 and 12). Geirsson et al (1977) analyzed the features of the cells in repair and compared them with cells of adenocarcinoma. There was a significant overlap between the two lesions, particularly in reference to nucleolar abnormalities. It is virtually impossible to arrive at a conclusive cytologic diagnosis in such cases and **patients should be evaluated further by colposcopy and cervical and endocervical biopsies. The Bethesda System** of cervicovaginal smear classification, described in Chapter 11, calls for separation of **“typical” from “atypical” repair**. This proposition is not reasonable because the cytologic pattern of repair is atypical by definition. For example, Rimm et al (1996) observed that 25% of patients with “atypical repair” pattern in smears harbored squamous intraepithelial lesions of low or high grade. Colgan et al (2001) reported that in a major survey of laboratories in the United States, **repair was the**

most common source of false-positive and false-negative smears.

In the absence of supporting clinical or histologic evidence, **the concept of repair, although occasionally correct, is a dangerous one as it may mislead even an experienced observer. Cell abnormalities of considerable magnitude not based on secure clinical and histologic data must be investigated further, regardless of label.**

ENDOCERVICAL POLYPS

This common benign tumor may originate in any area of the endocervical canal. **Histologically**, a polyp is composed of a central connective tissue stalk lined by gland-forming endocervical mucosa. Squamous metaplastic epithelium may replace portions of the outer lining and may extend to the glands. Inflammation of varying type and intensity is often observed in the stroma. Very uncommonly, cervix cancer may start in a polyp.

P.252

Figure 10-10 Repair reaction caused by an endocervical polyp. *A,B.* Marked abnormalities of metaplastic squamous cells with very large nuclei and bizarre cell shapes.

An **endocervical polyp cannot be recognized in cervical smears**, except for the rare events when a fragment of polyp may be observed (Ngadiman and Yang, 1995). Still, polyps may **cause nonspecific atypias of squamous and endocervical cells**. Small, **keratinized squamous cells** with fairly large pyknotic nuclei may be occasionally observed in cervical smears corresponding to areas of somewhat atypical squamous metaplasia on the surface of the polyp. In rare instances, the pressure of the polyp on adjacent endocervical epithelium may cause a **florid repair reaction** (Fig. 10-10A,B). Upon removal of the polyp, the cytologic abnormalities promptly disappear. Nevertheless, this uncommon occurrence represents a potentially important source of cytologic error.

EFFECTS OF INTRAUTERINE CONTRACEPTIVE DEVICES (IUD)

Sagiroglu and Sagiroglu (1970) documented that intrauterine contraceptive devices produce a chronic inflammatory reaction in the endometrium, resulting in the presence of leukocytes and macrophages in uterine lavage and in smears obtained directly from IUDs after removal. These authors suggested that the principal contraceptive effect of these devices is related to the presence of macrophages, which are capable of phagocytosis of spermatozoa. The effect of IUDs on the **endometrial cytology** and smear pattern has been discussed in Chapter 8 and is discussed again in reference to endometrial pathology in Chapter 13.

Endocervical Epithelium

The mechanical effect of IUD on endocervical epithelium may result in the shedding of columnar **endocervical cells with distended, vacuolated cytoplasm**. Occasionally, the vacuoles may be infiltrated by polymorphonuclear leukocytes, thus mimicking cells of endometrial adenocarcinoma (see Chap. 13). The cells may be similar to those observed in some instances of squamous metaplasia, described above. The pressure of the IUD on the endocervical epithelium may also result in **florid squamous metaplasia or the “repair reaction,”** as shown in Figures 10-9 and 10-10. Although Sagiroglu and Sagiroglu (1970) observed innumerable macrophages in smears obtained directly from IUDs after removal, there is no evidence that the population of these cells is significantly increased in routine cervical or vaginal samples of women wearing IUDs.

Other Findings

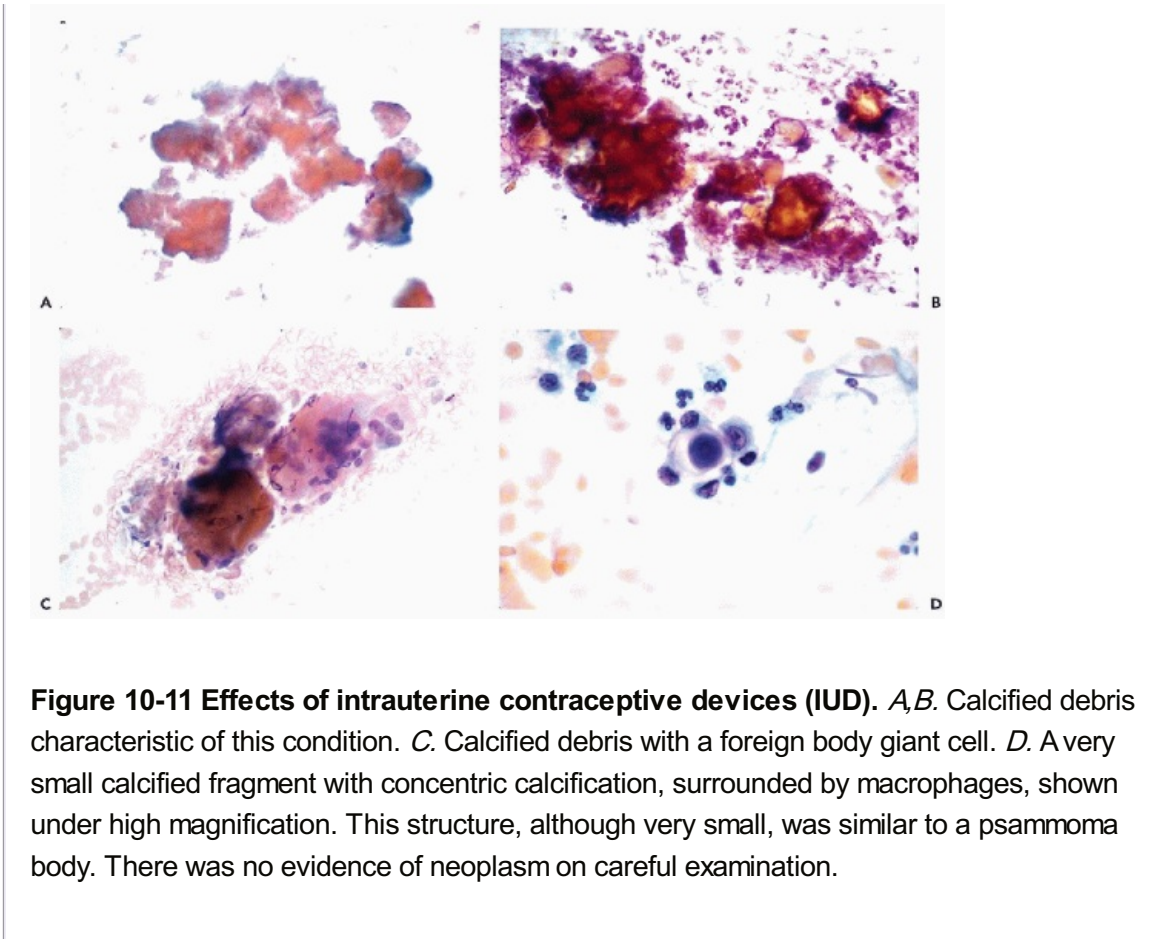

An important finding in women wearing IUDs is the presence of bacteria, *Actinomyces*, discussed in detail in the second part of this chapter and observed mainly in women wearing devices made of plastic for 3 or more consecutive years without replacement. The presence of *amoebae* in smears of IUD users was described by Arroyo and Quinn (1989) and by DeMoraes-Ruehsen et al (1980).

An occasionally disturbing finding in cervical smears from such patients is **amorphous debris that are sometimes calcified** (Fig. 10-11A-C) and occasionally form **small, concentrically calcified spherical bodies, akin to psammoma bodies**. The latter may be surrounded by macrophages (Fig. 10-11D). Schmidt et al (1980, 1982, 1986) has shown, by electron microscopy, that the calcified debris in IUD wearers represents fragments of plastic. There are usually few problems with the identification of the calcified debris. However, because psammoma bodies are commonly associated with ovarian and sometimes endometrial cancer (see Chaps. 13 and 15), the presence of debris mimicking psammoma bodies **calls for a precautionary examination of the patient after removal of the IUD**. The most commonly applied procedure is ultrasound of the pelvic organs.

A number of studies, beginning with the study by Melamed et al (1969) and subsequently repeatedly confirmed (Boyce et al, 1972; Ory et al, 1975; Sandmire et al, 1976) noted that **women using oral contraceptives or wearing IUD were at a higher risk of neoplastic cervical lesions than women using barrier contraceptives**, such as a diaphragm. These differences may be caused by exposure to human papillomaviruses, as discussed in Chapter 11. Therefore,

P.253

the screening and evaluation of smears from patients wearing IUDs must be thorough and careful, and any abnormalities that cannot be clearly attributed to the device itself should be further evaluated and investigated.

CHANGES INDUCED BY ENDOCERVICAL BRUSHES

The widespread use of endocervical brush instruments had for its purpose securing cells from the endocervical canal to insure adequacy of sampling. However, rigorous use of these instruments may also result in cytologic abnormalities that may cause difficulties of interpretation. The resulting smear may contain **thick clusters of endocervical cells, sometimes of complex configuration (such as loose peripheral cells, a phenomenon known as “feathering”) that may mimic changes attributed to endocervical carcinoma** (Fig. 10-12A-C). It is possible that some of the cellular changes attributed to various abnormalities of the uterine endocervix, such as tubal metaplasia or microglandular hyperplasia are actually brush-induced artifacts. These clusters may persist in liquid preparations and may also cause problems of interpretation. **The fundamental principle of cytopathology requires that all cell abnormalities in smears must find their counterpart in histologic material. Lesions incidentally found in histologic material are not necessarily the source of cytologic abnormalities and vice versa, without appropriate documentation.**

Wilbur (1995) also pointed out that endocervical brushings present the observer with numerous difficult-to-interpret cell images that may be mistaken for various neoplastic lesions. Babkowski et al (1996) pointed out that **the most complex cell clusters** are derived from the upper reaches of the endocervical canal and maybe associated with tubal metaplasia (see above). Such clusters are occasionally too dense or too complex to interpret as normal and may either lead to unnecessary biopsies or result in a request for additional sampling. If the additional sampling is performed **before the brush-induced injury to the cervical epithelium has healed** (6 to 12 weeks), the resulting atypia of **repair** may cause additional interpretative difficulties (Fig. 10-12D). In my experience, the **interpretation of thick, 3-dimensional**

endocervical cell clusters should be conservative, unless the smear also contains abnormal cells singly or in small clusters that are easier to evaluate. It is rare for a neoplastic

P.254

lesion to occur in the form of tightly knit clusters of endocervical cells, without some ancillary evidence of disease, as discussed in the appropriate chapters.

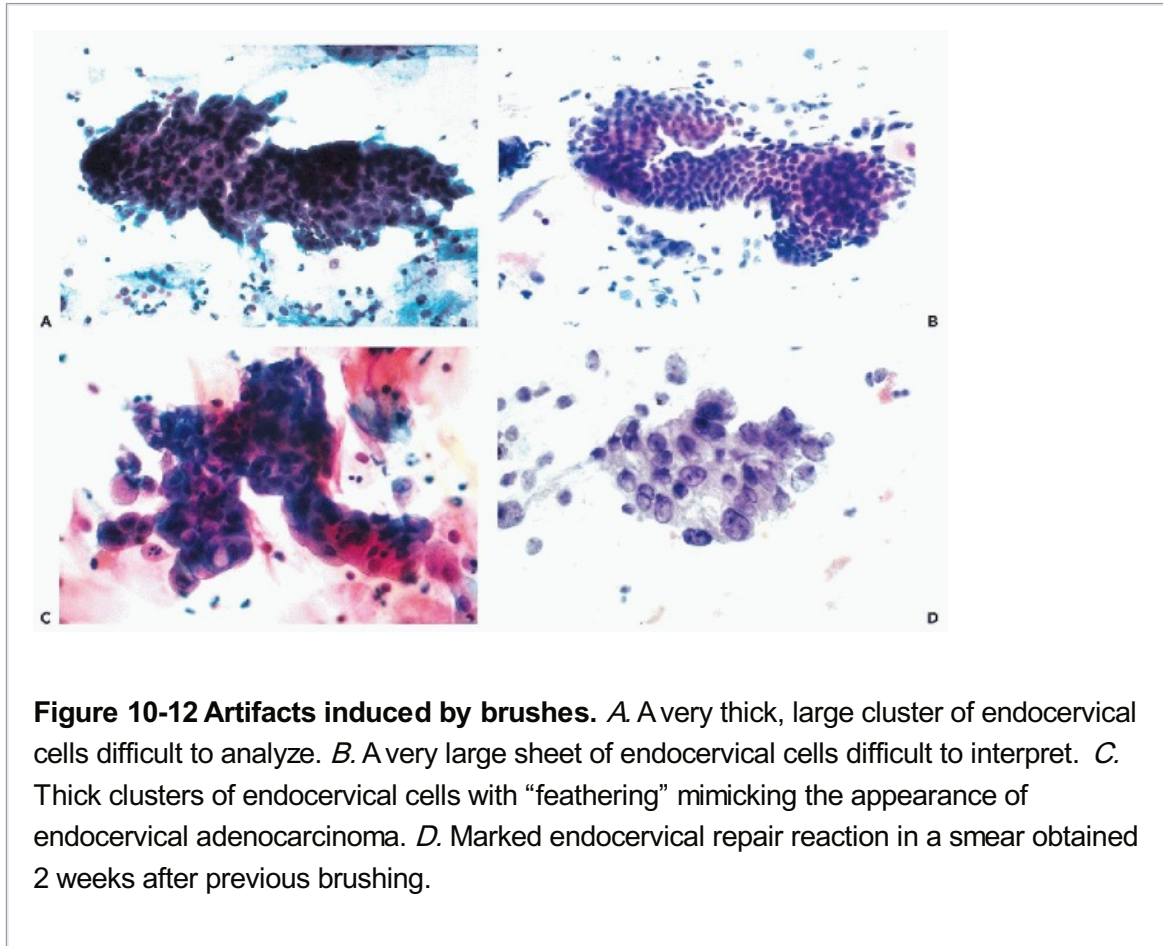

Figure 10-12 Artifacts induced by brushes. *A.* A very thick, large cluster of endocervical cells difficult to analyze. *B.* A very large sheet of endocervical cells difficult to interpret. *C.* Thick clusters of endocervical cells with “feathering” mimicking the appearance of endocervical adenocarcinoma. *D.* Marked endocervical repair reaction in a smear obtained 2 weeks after previous brushing.

Another consequence of rigorous brushings is the presence of normal **endometrial cells** in the sample. Such small cells, when seen in the endocervical sample may be **mistaken for small cancer cells**. This issue is discussed further in Chapter 8.

In general, the endocervical brush instruments, hailed as an important advance in cervicovaginal cytology because they insure sampling of the endocervical canal, are also a source of potential diagnostic errors.

INFLAMMATORY PROCESSES OF THE FEMALE GENITAL TRACT

INFLAMMATORY AGENTS

Inflammatory processes within the female genital tract may be caused by infections with a variety of microorganisms and parasites or by physical and chemical agents. Sometimes the causes of the inflammation remain unknown as in Behçet's disease (Sakane et al, 1999). In this chapter, the basic mechanism of inflammation and diseases caused by bacterial, fungal, viral, and parasitic agents will be described. The physical and chemical agents are discussed in Chapter 18. Most of the organisms responsible for inflammatory processes may be recognized in Papanicolaou-stained smears although, occasionally, special stains or procedures may be

required for identification. The principal infectious agents are as follows:

Bacterial agents

Cocci and coccoid bacteria

Gram-positive cocci: species of *Streptococcus* and *Staphylococcus*

Gram-negative cocci: *Gonococcus*

Gardnerella vaginalis (*Haemophilus vaginalis* or *vaginalis*)

Diphtheroids

Calymmatobacterium granulomatis Donovan (*granuloma inguinale*)

Mycoplasma and *Ureaplasma*

Chlamydia trachomatis

Acid-fast organisms: *Mycobacterium tuberculosis*, *Mycobacterium avium*

Actinomyces

Spirochaeta pallida (syphilis)

Organisms that are normally saprophytic but may be associated with infections:

Lactobacillus (*Döderlein bacillus*) and *Leptothrix*

Other uncommon bacterial agents

Fungal agents

Candida species: *C. albicans* (*monilia*), *C. glabrata* (*Torulopsis glabrata*)

Aspergillus species

Coccidioidomycosis

Paracoccidioidomycosis

Cryptococcus species

Blastomyces

Viral agents

Herpesvirus types I, II, VIII

Cytomegalovirus

Human polyomavirus

Measles

Adenovirus

Molluscum contagiosum (vulva)

Human papillomavirus, various types (see Chap. 11)

Other rare viruses

Parasitic infections and infestations

Protozoa

Trichomonas vaginalis

Entamoeba histolytica

Entamoeba gingivalis

Balantidium coli

Helminths (worms)

Schistosoma haematobium, *S. mansoni*, *S. japonicum*

Filariae

Intestinal worms

Enterobius vermicularis (pinworm)

Trichuris trichiura (whipworm)

Teniae (flat worms)

T. solium (intermediate host: swine)

T. saginata (intermediate host: cattle)

T. echinococcus (intermediate host: dog)

Other uncommon parasites

Trypanosomiasis

P.255

With the spread of the **acquired immunodeficiency syndrome (AIDS)**, in which normal immune defenses of the human body are reduced or abolished, unusual organisms (not listed above) may be encountered.

MECHANISMS OF INFLAMMATION

The female genital tract is a common site of inflammatory processes that may involve the **vulva, vagina, uterine cervix, endometrium** and spread to organs located in the bony

pelvis, such as the **fallopian tubes, ovaries, and parametria**. Many, although not all, of the agents causing inflammation may be sexually transmitted (Borchardt and Noble, 1996).

The **predisposing factors** are: not fully mature squamous epithelium of the vagina and cervix, such as that seen in prepubertal girls or in menopausal women; injury to the endocervical canal, especially during pregnancy or delivery; or trauma of any kind. The variations of the **vaginal acidity (pH)** are also significant. Alkaline pH, such as observed during the menstrual flow, favors the growth of the common parasite, *Trichomonas vaginalis*, which does not prosper in an acid pH of less than 5. Other microorganisms have other pH requirements.

Three **basic pathways of infection** of the genital tract are recognized:

1. **Direct invasion** of the genital tract by pathogens, often sexually transmitted
2. Spread of an infectious process **from an adjacent organ**
3. **Blood-borne** infections

Regardless of the pathway or the causative organism, all infectious processes may lead to an acute or chronic inflammatory reaction. Although any component of the female genital tract can be affected by an inflammatory process, **certain agents may favor one type of tissue to another.** For example, *Trichomonas vaginalis* infestation affects mainly the squamous epithelium of the vagina, cervix, and urethra. Many **pus-producing bacteria**, such as staphylococci and streptococci, find favorable conditions for survival in the **endocervical canal**, whence the infection may spread into the endocervical glands. From the cervix, the infectious agents may ascend the endocervical canal and reach the **endometrium, the fallopian tubes, and thence the pelvic organs, causing pelvic inflammatory disease.** Other organisms may have a different behavior pattern, as will be discussed below. Because the epithelial changes accompanying inflammation may result in considerable cytologic atypias, they are reported in some detail.

Sequence of Events in Inflammatory Processes

An inflammatory process is a complex reaction of the living tissue to various forms of injury that may be caused by a variety of agents, many of them listed above. An excellent summary of the current state of knowledge pertaining to mechanisms of inflammation can be found in a paper by Luster (1998). Only a simple summary of the key events is provided here.

Acute Inflammation

The first event in an acute inflammatory process is injury to the tissue. The common cause of injury is pathogenic organisms or physical and chemical agents. The injury causes **cell death or necrosis** which **attracts polymorphonuclear leukocytes**, principally neutrophils, that invade the affected tissue exiting from the dilated **regional capillary vessels**. This function is governed by chemotactic agents known as **chemokines** (Luster, 1998). The role of the neutrophils is to phagocytize, neutralize and destroy the agent(s) causing cell death. There are several consequences of this initial sequence of events. The **capillary vessels** may be injured and blood may seep into the affected area. The neutrophils often die while performing the initial defensive role and release into the surrounding tissues a number of proteolytic enzymes that damage the tissues further, **increasing the area of necrosis**. The second echelon of defenses is vested in **B and T lymphocytes and in macrophages**,

which enter the area of injury. The macrophages are activated to phagocytize the debris and eliminate the damages. In **some parasitic infestations, eosinophilic leukocytes** may play a key role.

There are several possible **outcomes of the initial, acute inflammatory process**:

- The injurious agent is eliminated, the inflammatory process is contained and healing commences, heralded by activation of **stromal fibroblasts**. The fibroblasts will provide the **collagen** necessary to replace the necrotic, injured tissue, resulting in the formation of a **scar**.
- The acute inflammatory process continues with resulting increased necrosis and formation of **purulent exudate or pus**. Pus is a semiliquid mixture of blood serum, necrotic neutrophils, macrophages and debris derived from the injured tissue. Accumulation of pus within a limited area of tissue results in an **abscess** that may be contained within a **connective tissue capsule** formed by fibroblasts. A breakdown of an abscess towards an open surface results in an **ulcer**. Healing of an abscess usually requires drainage of the pus, followed by a connective tissue growth into the area occupied by the abscess and formation of a scar.
- The acute inflammation may subside and become **chronic**.

Chronic Inflammation

Chronic inflammation is characterized by reduction in the population of polymorphonuclear leukocytes in favor of **lymphocytes** and **macrophages**, often accompanied by **activation of fibroblasts** and new growth of **capillary vessels** into the affected area. In some cases, the process may be designated as **granulation tissue**, because, when located on the surface of an organ, it may be visible to the naked eye as a red granule (see below).

There are several **forms of chronic inflammation**. Some of them are designated as **specific** because of the characteristic changes caused by the nature of the invading microorganism. For example, the infection with **mycobacterium tuberculosis**, results in **granulomatous inflammation**, which forms a recognizable pattern of abnormalities (granulomas, to be described below). Other chronic inflammatory processes are **nonspecific**, i.e., without features that would allow the identification of the causative organism. Chronic inflammation may have major consequences on cytologic patterns in cervicovaginal smears.

Figure 10-13 Histology of severe cervicitis. A. Acute inflammatory reaction involving the squamous epithelium and characterized by marked dilatation of capillary vessels. The

patient had trichomoniasis. *B.* Severe cervicitis showing damaged surface of the squamous epithelium and thick inflammatory infiltrate involving the stroma and the epithelium.

Acute Inflammatory Processes in the Uterine Cervix and Vagina

Histology of Acute Cervicitis and Vaginitis

Of these two organs, the uterine cervix is more often affected than the vagina and is more often sampled by biopsy. The **dominant feature** of acute inflammatory processes in the cervix is the presence of a **dense inflammatory infiltrate**, composed mainly of neutrophils in the stroma of the organ. Dilated capillary vessels with margination of leukocytes are usually observed. Focal necrosis and pus formation may occur.

Changes in Squamous Epithelium

The response of the squamous epithelium to injury is particularly common in *Trichomonas vaginalis* infestations but may also be caused by other inflammatory agents. The first event in inflammation is a **vascular response**. The normally small connective tissue plugs, or **papillae**, that carry the capillary vessels supplying the squamous epithelium with blood, become markedly elongated. The capillary vessels within the papillae become distended with blood, followed by **margination and migration of polymorphonuclear leukocytes** resulting in acute papillitis (Fig. 10-13A). The entire epithelium may become permeated by polymorphonuclear leukocytes. Marked accumulation of fluid (**edema**) in between the epithelial cells is sometimes noted. The squamous epithelium may shed loosely attached layers of superficial cells, leading to **epithelial erosion**. This may be followed by **necrosis** of some part or the entire epithelial thickness which, combined with an inflammatory infiltrate, results in a formation of a **crater: an ulcer**. Purulent exudate

P.257

may coat the necrotic surface (Fig. 10-13B). Inflammatory changes affecting the epithelium of the vagina have a similar histologic pattern.

The Endocervix

The stroma of the endocervix is infiltrated with polymorphonuclear leukocytes and shows other changes described above. Primary necrosis of the endocervical mucosa is uncommon. The endocervix may be coated by a thin layer of pus, but the structures mainly affected are the **endocervical glands**, wherein the acute inflammatory changes and sometimes **abscess formation** may occur. The acute inflammatory processes may cause substantial changes in the endocervical glandular cells: swelling, enlargement, and necrosis of these cells may occur.

Cytology of Acute Cervicitis and Vaginitis

In the presence of an acute inflammation, the smears have a “dirty” appearance, caused by **inflammatory exudate** (Fig. 10-14A,B). The exudate is composed of a **mixture of polymorphonuclear leukocytes, necrotic cells or cell debris, necrotic cells, and clumps of bacteria** in a background of proteinaceous material and **lysed or fresh blood**. Care must be taken **not to confuse the physiologic presence of scattered polymorphonuclear leukocytes** in premenstrual and menstrual smears and in smears of the mucus plug of the cervix with an acute inflammatory process. In acute inflammation, the squamous cells may display marked **cytoplasmic eosinophilia**, involving the normally basophilic squamous cells of

the intermediate and parabasal type (Fig. 10-14C). This feature of the squamous cells is particularly evident in *Trichomonas vaginalis* infestation.

Figure 10-14 Various manifestations of inflammatory reaction in cervicovaginal smears. *A.* Typical smear pattern in acute cervicitis. The background contains polymorphonuclear leukocytes and necrotic cell debris. Squamous cells and a small cluster of degenerating parabasal cells may be observed. *B.* Atypia of squamous cells in cervicitis caused by *Trichomonas* infestation. Note nuclear enlargement and pallor caused by impending necrosis of the squamous cells. The background is typical of an acute inflammatory reaction. *C.* Marked eosinophilia of squamous cells in a case of *Trichomonas* infestation. A single parasite may be seen in the field of vision (*arrow*). *D.* Marked increase in the population of parabasal squamous cells in a young woman with severe trichomonas cervicitis.

During the childbearing age, an increase in the population of parabasal squamous cells is a frequent alteration of the cervical smear pattern in acute inflammation that, in extreme cases, may suggest a low level of estrogenic activity and may even mimic the pattern of postmenopausal atrophy (Figs. 10-14D and 10-15). The **sources** of the parabasal cells are superficial erosions and ulcerations of the squamous epithelium, resulting in the exposure of the deeper epithelial layers.

In postmenopausal women with a basically atrophic

P.258

smear pattern, an acute inflammation may have two effects. The first is an **increased maturation of the squamous epithelium** with reappearance of intermediate and even superficial squamous cells (see Fig. 10-15). The reason for this phenomenon is in all probability an increased blood supply to the squamous epithelium that is noticeably present in *Trichomonas* infestation. As discussed in Chapter 9, one should not attempt to estimate the level of estrogenic activity in smears in the presence of a marked inflammation. The second effect of acute inflammation may be an **increase in cell necrosis and, hence, cell debris which, combined** with the phenomena of naturally occurring cell damage in advanced atrophy

discussed in Chapter 8, may make the interpretation of such smears particularly difficult.

The presence of a marked inflammatory exudate and cell necrosis may also occur in advanced cancers of the cervix and the endometrium. Therefore, careful screening of such smears is mandatory.

Cytologic Atypias in Acute Inflammation

Depending on the etiology of an inflammatory lesion, cytologic changes may affect the squamous cells, the endocervical cells, or both cell types. For reasons of clarity, the changes will be described separately for the various categories of cells.

Squamous Cells

Acute inflammation affecting the squamous epithelium of the vagina and the ectocervix may bring about **necrosis of superficial, intermediate, and parabasal cells**. Somewhat

enlarged, blown-up homogeneous nuclei without any nuclear structure may be noted (see Figs. 10-14A and Fig. 16A). Nuclear **pyknosis**, often associated with **break-up of chromatin** (karyorrhexis or apoptosis), is often present. The affected nuclei are quite dark and appear somewhat irregular because of fragments of chromatin protruding into the cytoplasm (see Figs. 10-14D and 10-16C). The lack of internal structure in the pyknotic nucleus and the preservation of a normal nucleocytoplasmic ratio are important to note in order to avoid any confusion with neoplastic changes. The pyknotic nuclei are often surrounded by **narrow clear cytoplasmic zones (halos)** (Fig. 10-16B) **which should not be confused with large perinuclear clear zones characteristic of koilocytosis**, described in Chapter 11. Binucleation, as well as slight cellular enlargement, may occur.

Necrosis and shedding of the superficial layers of the squamous epithelium, often observed during acute inflammation, result in an **increase** in the proportion of **parabasal cells** in smears of young women (see above and Fig. 10-15). In cervical smears, the parabasal cells occur singly or in **aggregates or plaques** composed of cells with **cytoplasmic processes** of various lengths. Such cells are of irregular shapes and, when in plaques, give the appearance of a jigsaw puzzle (see Fig. 10-4D). The term “**metaplastic cells**” is usually applied to such clusters, although their origin from squamous metaplasia is not always secure or evident. For further discussion of squamous metaplasia, see above. In well-preserved parabasal cells, the cytoplasm is chiefly basophilic; the density of the stain is often greater in the perinuclear area. Fine, **small cytoplasmic vacuoles** may be noted. The nuclei may appear somewhat enlarged; numerous **chromocenters** and **occasionally single small nucleoli** may be noted. Nuclear **pyknosis and karyorrhexis (apoptosis)** may also occur in parabasal cells (Fig. 10-16C). Binucleation or even multinucleation may occur.

Endocervical Cells

Acute endocervicitis may produce a **striking enlargement of the endocervical cells and their nuclei. Conspicuous cytoplasmic vacuoles**, sometimes infiltrated by polymorphonuclear leukocytes, may be observed (Fig. 10-17A). **Multinucleated endocervical cells** may occur. **Pyknotic nuclei are uncommon but bare nuclei** stripped of cytoplasm are often observed. The correct identification of such nuclei is facilitated by comparison with well-preserved endocervical cells. The **most conspicuous nuclear changes** consist of the presence of numerous **chromocenters** and one or more quite large and **conspicuous nucleoli** (Fig. 10-17B). **Mitotic figures** may occur. Similar findings occur in “repair,” discussed above. Such findings are often disconcerting to the observer and the **differentiation of such cell abnormalities from those occurring in precancerous lesions or adenocarcinoma is at times very difficult** (see Chap. 12, where such mistakes are discussed). The presence of single abnormal cells favors a neoplastic process, but there are exceptions to the rule.

A final diagnostic decision as to the nature of endocervical cell changes cannot always be made on smears.

P.259

While the absence of single abnormal cells speaks strongly in favor of a benign process, follow-up of such patients, which should include **colposcopy and biopsy**, is often indicated.

Figure 10-16 Squamous epithelial cell abnormalities associated with severe cervicitis. *A.* Nuclear pallor and enlargement indicative of impending cell necrosis. *B.* Prominent perinuclear halos common in trichomonas infestation. *C.* Hyperchromasia of parabasal cells, some showing nuclear fragmentation or apoptosis under high magnification.

Chronic Inflammatory Processes

Chronic inflammatory processes of a minor degree are exceedingly common in the female genital tract and **produce few, if any, specific morphologic changes in epithelial cells.** The smears may show evidence of **benign abnormalities such as squamous metaplasia and repair, although their relationship to inflammatory processes is not always evident.** These conditions are discussed above. The only constant evidence of chronic inflammation is the presence of **lymphocytes, occasional plasma cells, and macrophages** in the background of the smear.

Figure 10-17 Abnormalities of endocervical cells commonly seen in inflammation. *A.* Marked vacuolization of cytoplasm. *B.* The presence of prominent nucleoli.

Macrophages (Histiocytes)

In the description of the menstrual cycle, it was noted that great numbers of small macrophages (**exodus**) may be found

P.260

in cervicovaginal smears toward the end of the menstrual bleeding. In chronic inflammation, **mononucleated macrophages** occur commonly and are usually quite a bit larger than their “menstrual” counterpart (see Fig. 8-22A,B). They are characterized by a very finely **vacuolated, lacy cytoplasm, often containing ingested debris** and a rather **characteristic nucleus**. The latter is oval or bean-shaped and has a prominent nuclear membrane that stands out readily against the delicate bluish cytoplasm. Within the nucleus, there are a few sharply defined **chromocenters** and a few thin threads of chromatin. Occasionally, it is difficult to differentiate small macrophages from parabasal cells originating from squamous metaplasia of the endocervix. **Rarely, mitotic figures may be observed** in macrophages in smears. Nasiell (1961) pointed out that the mononucleated macrophages may be mistaken for cancer cells and that the differential diagnosis is based on evidence of phagocytic activity.

As described in Chapter 8, **multinucleated macrophages** are frequently observed in smears of postmenopausal women and may achieve very large sizes, even in the absence of inflammation (see Fig. 8-28C). However, in nonspecific chronic inflammatory processes in women of all ages, multinucleated macrophages may occur, sometimes in large numbers. A special type of multinucleated macrophages with peripheral placement of nuclei (**Langhans' cells**) may be observed in specific inflammatory processes such as tuberculosis (see below). The multinucleated macrophages **may show abnormal nuclear features such as nuclear enlargement and hyperchromasia that may mimic a malignant tumor**. This is particularly evident in the presence of **granulation tissue** (see below). The significance of macrophages (histiocytes) in the diagnosis of endometrial carcinoma is discussed in Chapter 13.

Figure 10-18 Nuclear abnormalities in atypical macrophages in a patient with granulomatous reaction in the uterine cervix. A A multinucleated macrophage with nuclei of variable sizes. **B,C.** Very large hyperchromatic nuclei derived from macrophages.

Granulation Tissue and Atypical Macrophages

Following a disruption of the epithelial surface and exposure of the underlying connective tissue, and usually as a consequence of a chronic inflammation, surgery or radiotherapy, the repair of the epithelial defect is preceded by formation of granulation tissue which may be visible on the **surface of the organ as a granulated red protrusion**, accounting for the name of the lesion (Singer and Clark, 1999). The granulation tissue is exposed to trauma and it bleeds easily as a consequence of rich vascularization. The identification of granulation tissue is of particular diagnostic importance after surgery or radiotherapy because it may be clinically mistaken for persisting or recurrent malignant tumor.

Histology.

The granulation tissue consists of an **exuberant proliferation of fibroblasts, accompanied by formation of numerous young capillaries and by a marked inflammatory infiltrate consisting of** leukocytes, lymphocytes, and macrophages of the mono- and multinucleated type.

P.261

Cytology.

Smears obtained from granulation tissue are characterized by a marked inflammatory exudate. Leukocytes of various types are commonly seen in the background of smears. **Poorly preserved epithelial cells**, occasionally elongated **fibroblasts**, and numerous **macrophages** are present. The latter cells occasionally contain **multiple, highly abnormal, enlarged, and hyperchromatic nuclei** (Fig. 10-18A,B). A breakdown of these highly abnormal macrophages may result in the presence of isolated, **large hyperchromatic nuclei** that, for all intents and purposes, mimic nuclei of cancer cells (Fig. 10-18C). The differentiation of such cells or nuclei from cancer cells is based on **finding transition forms between clearly benign multinucleated macrophages and the rather uncommon, highly atypical, forms**. It is sometimes of value in the **differential diagnosis between atypical multinucleated macrophages and multinucleated cancer cells** to notice the **placement of nuclei**, which, in the macrophages, tend to be located at the periphery of the cell, whereas in the cancer cells they tend to be more centrally located, although there are many exceptions to this rule. Evidence of **phagocytic activity** is also in favor of macrophages, although it may occasionally be observed in cancer cells as well. In case of doubt, a biopsy may be necessary.

Figure 10-19 Follicular cervicitis. *A.* The presence of a large deposit of lymphocytes in the smear of the cervix is characteristic of this disorder. *B,C.* High-power views of lymphocytic population. In *C*, mitotic activity in follicle center cells may be noted. *D.* Biopsy of cervix showing deposits of lymphocytes.

Unusual Forms of Chronic Cervicitis

Follicular Cervicitis

This is an uncommon benign disorder wherein formation of **mature lymph follicles occurs in the subepithelial location in the uterine cervix** (see Fig. 10-19D). Roberts and Ng (1975) observed that follicular cervicitis is significantly more common in postmenopausal women, although it may occur in women of all age groups and menstrual status. Clinically, the disorder may be observed as pinheadsized white or gray elevations on the surface of the cervix. If the epithelium of the cervix is ulcerated or if the lymphoid tissue is forcibly removed by scraping, **clusters of lymphocytes may be observed in cervical smears**. The pathogenesis and full clinical significance of follicular cervicitis is not understood. There have been several observations linking follicular cervicitis with an infection with *Chlamydia trachomatis*. To what extent, if any, follicular cervicitis reflects

P.262

a general disorder of the immune system is not known at the time of this writing.

Figure 10-20 An accumulation of plasma cells in a cervicovaginal smear.

Cytology

In smears, the disorder is characterized by the presence of **pools of lymphocytes** which, in most cases, can be identified as such under low power of the microscope (Fig. 10-19A).

The diagnosis becomes more difficult if the lymph follicles are broken up. The smear then displays a **mixture of lymphocytes and large, follicle center cells**, the latter derived from the germinal centers of the lymph follicles (Fig. 10-19B). The follicle center cells have the appearance of mononucleated **large lymphocytes with a delicate, vacuolated cytoplasm and large vesicular nuclei, occasionally provided with one or more prominent nucleoli**. The follicle center cells may show **numerous mitoses** (Fig. 10-19C). Small macrophages with evidence of phagocytic activity may also be present. The diagnosis is based usually on smear pattern and the monotonous aspect of the benign lymphocytes. The **differential diagnosis comprises malignant lymphoma and leukemia** involving cervix or vagina. In both these disorders, the malignant lymphoid cells are dispersed and there is little evidence of clustering of lymphocytes.

Plasma Cell Cervicitis

Qizilbash (1974) reported a case of what appears to be an extremely rare disorder of the cervix, characterized by the presence of **plasma cells of varying degrees of maturity**. The plasma cells infiltrated the cervical stroma and were observed in the cervical smears. Some of the plasma cells were multinucleated and bizarre. There was no evidence of generalized plasma cell myeloma. It must be pointed out that plasma cells are a common component of the cell population infiltrating the uterine cervix in **chronic cervicitis** of bacterial origin and may find their way into cervical smears (Fig. 10-20). We have also observed **plasma cells in smears in an occasional case of microglandular hyperplasia**, as discussed above.

SPECIFIC INFECTIONS OF THE CERVIX AND THE VAGINA

Bacterial Infections

Normal Bacterial Flora

Although the dominant organism in the normal female genital tract is *Lactobacillus* (see Chap. 8), comprehensive studies by Ohm and Galask (1975), Roupas et al (1985), and Bibbo and Wied (1997) have shown that the bacterial flora of the vagina also contains small properties of other **aerobic and anaerobic microorganisms**. Although some of these organisms are considered to be pathogenic, their mere presence within the vagina or cervix is usually harmless. Many of the bacterial agents may be identified in cytologic preparations. The principal species, the diseases caused by them, and their effect on cervicovaginal smears will be described below.

Lactobacillus (Döderlein), Also Known as Bacillus vaginalis (B. vaginalis)

As described in Chapter 8, *Lactobacillus* is the normal inhabitant of the lower genital tract. Lactobacilli are **aerobic, gram-positive rods**. In genital smears stained with Papanicolaou stain, *Lactobacillus* organisms are identified as **slender basophilic rods of various lengths** distributed on cell surface and in smear background (see Fig. 8-37). The frequency of occurrence of *Lactobacillus* as the principal vaginal microorganism varies with the population studied. In patients with good vaginal hygiene, approximately 50% harbor this microorganism. In clinic populations attended by women with poor vaginal hygiene and high levels of sexual exposure, this figure drops significantly to approximately 20% or less.

Lactobacilli ferment cytoplasmic glycogen and, therefore, cause **cytolysis** of glycogen-containing squamous cells described in Chapter 8 (see Fig. 8-31B). The most mature superficial squamous cells and the parabasal cells are often spared. Therefore, **cytolysis is mainly observed in situations in which intermediate cells predominate, to wit: the premenstrual phase of the menstrual cycle, pregnancy, and early menopause**. The moth-eaten appearance of the cytoplasm of the intermediate squamous cells and the presence of isolated nuclei remaining after lysis of the cytoplasm by the bacteria are characteristic of this condition. Cytolysis is seldom observed in postmenopausal women with an atrophic smear pattern. It is a matter for some debate whether *Lactobacillus* is ever responsible for inflammatory states. Occasionally, **clear vaginal discharge** apparently due to excessive glycolysis may be observed.

Gardnerella vaginalis (Previously Known as Corynebacterium vaginale and Haemophilus vaginalis)

This **anaerobic organism** is encountered in about 6% of women of childbearing age and causes vaginitis and cervicitis in some of them. The organism is a Gram-negative or Gram-variable short rod that, in Papanicolaou stain, stains dark blue. The organism tends to **accumulate on the surfaces of squamous epithelial cells**, giving them a peculiar and rather uniquely diagnostic appearance of a “**clue cell**”

P.263

(Gardner and Dukes, 1955; Gardner and Kaufman, 1969; Dunkelberg, 1965). In some cases, the **entire surface of the cell is obscured by the Gardnerella**; in most instances, only a part of the cell surface is covered by the microorganism (Fig. 10-21). The same small microorganisms in variable numbers are usually observed in the background. There is no cytolysis. It must be pointed out, however, that **lactobacilli may also accumulate on the surfaces of squamous cells** (see Fig. 8-37B). However, the **lactobacilli appear as distinct**

rods, whereas in the clue cells, the surface is hazy and the individual *Gardnerella* organisms cannot be clearly discerned. Gardner and Kaufman emphasized that in the presence of mixed infections with pyogenic bacteria or *Trichomonas vaginalis*, the clue cells often cannot be identified. The organisms play an important role in **bacterial vaginosis**, described below.

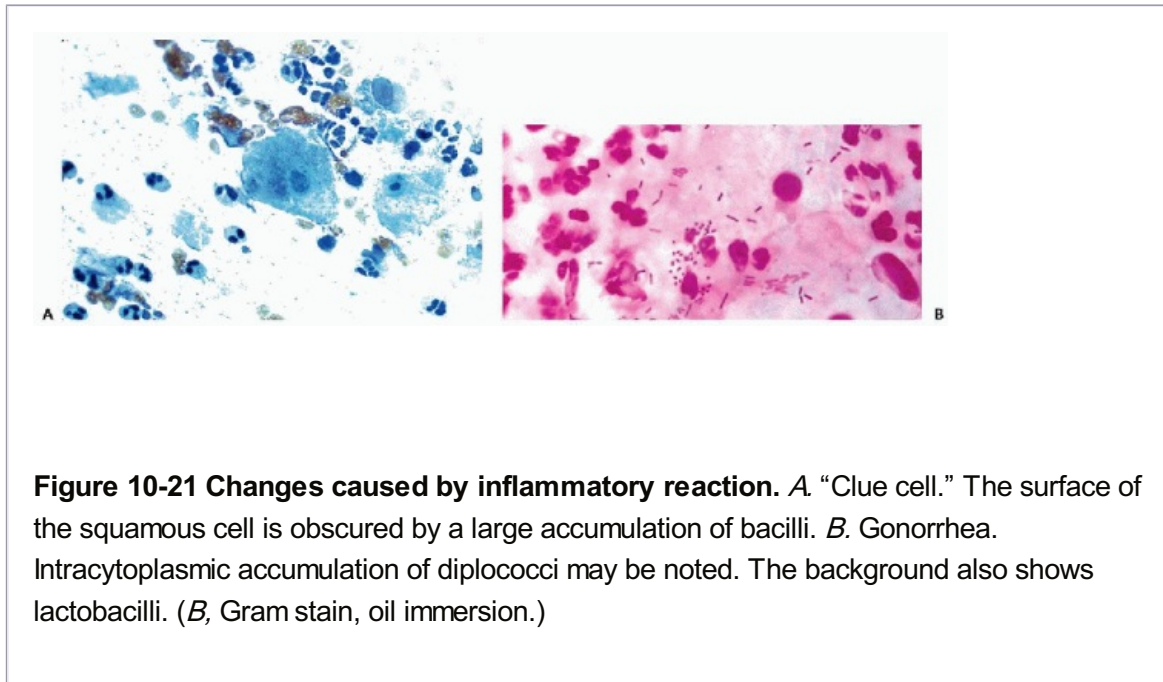

Figure 10-21 Changes caused by inflammatory reaction. A. “Clue cell.” The surface of the squamous cell is obscured by a large accumulation of bacilli. B. Gonorrhea. Intracytoplasmic accumulation of diplococci may be noted. The background also shows lactobacilli. (B, Gram stain, oil immersion.)

Diphtheroids

Short rods, arranged in the form of “**Chinese characters**” with a terminal clublike thickening, have been described in a small percentage of vaginal and cervical smears by Leppäluoto (1974). The staining is uneven and the thickened end is darker than the body of the rod. The pathogenicity of this organism has not been established.

Corynebacterium diphtheriae

True **diphtheria** of the vagina is exceedingly rare. The causative organism resembles morphologically the diphtheroids described above. In contrast with the diphtheroids *C. diphtheriae* causes a **necrotizing inflammation of the vaginal epithelium** similar to that observed in the nasopharynx.

Gram-Positive Cocci

A large variety of Gram-positive cocci may be observed in cervicovaginal smears. The organisms cannot be specifically classed without identification by culture. **Staphylococci** and **streptococci** are the common varieties with *Staphylococcus epidermidis*, the most common variant (Ohm and Galask, 1975). Most cocci appear as **clusters or chains of very small, round or oval organisms, staining dark blue or gray in Papanicolaou stain**, usually occupying the background of the smear, with few organisms superimposed on the surfaces of the squamous cells. In extreme cases, the background of the smear appears “**dirty**” because it is filled with cocci. The gram-positive cocci may be the cause of **pyogenic infections** of the female genital tract and are an important cause of **pelvic inflammatory disease**. The cocci are frequently associated with other organisms and with *Trichomonas vaginalis* (Gardner and Kaufman, 1969).

Gram-Negative Cocci

Neisseria gonorrhoeae (*N. gonorrhoeae*) or gonococcus is the causative organism of **acute and chronic gonorrhea**, the most common of all sexually transmitted diseases. The organism is a **Gram-negative diplococcus** that is an **intracellular parasite**. It may be observed in Papanicolaou-stained material adhering to the surface or in the cytoplasm of intermediate and parabasal squamous cells as **tiny coffee-bean organisms arranged in pairs** (Fig. 10-21B). Heller (1974) observed the organisms mainly in cells from squamous metaplasia of the endocervical canal, but I have repeatedly seen gonococci in squamous cells apparently originating in mature squamous epithelium. Oil immersion is required for identification of gonococci in cervical smears. Morphologic separation of *N. gonorrhoeae* from other species of *Neisseria*, notably the very important *N. meningitidis*, is not possible and it is advisable to confirm the diagnosis by culture.

During the acute stage of gonorrhea, acute purulent **urethritis**, both in man and in woman, is a nearly universal manifestation of infection. While in men the disease is usually symptomatic, it may be completely asymptomatic in women. Litt et al (1974) emphasized that in children and adolescents, gonorrheal **vaginitis** may be more common than in adult women. In women, the disease may cause cervicitis, endocervicitis, and inflammation of Bartholin's glands and may spread via the fallopian tube to the pelvic organs and cause **tubo-ovarian abscesses** or even acute peritonitis. Gonorrhea may cause **acute arthritis**, usually limited to a single joint.

Neither acute nor chronic gonorrhea cause specific cytologic abnormalities. The smear pattern is that of an acute or chronic cervicitis or vaginitis.

P.264

Mobiluncus Species

These curved, Gram-variable anaerobic bacteria, sometimes described as **boomerang-shaped**, may aggregate on the surfaces of squamous cells. The organisms are present in a small percentage of normal women but are nearly universally observed in women with bacterial vaginosis, described below.

Mycoplasma and Ureaplasma

Mycoplasma, previously known as pleuropneumonia-like organism (PPLO), is the **smallest free-living organism**. It causes **atypical pneumonias** and may cause immune disturbances such as formation of cold-agglutinins. Its role as an infectious agent in the female genital tract has been investigated by Gregory and Payne (1970) and by Leppäluoto (1972). ***Mycoplasma hominis***, type I, has been identified in 30% of asymptomatic women and **in 92% of women with sexually transmitted diseases**. There are no known cytologic changes attributable to *Mycoplasma*; however, the organism participates in bacterial vaginosis.

A related microorganism, *Ureaplasma urealyticum*, may also be documented by culture in 37% of normal women and 56% of women with known infection (Roupas et al, 1985). No documented cytologic abnormalities are associated with this organism.

Bacterial Vaginosis

Bacterial vaginosis is the **most frequent cause of vaginitis and cervicitis** during the childbearing age. The disorder is caused by profound **changes in the vaginal flora**, normally dominated by lactobacteria, in favor of a **mixed bacterial flora dominated by *G. vaginalis***,

***Mobiluncus* species, mycoplasma, and a large variety of other organisms, mainly Gram-negative rods** (Hill, 1993). Sobel (1997) discussed the chemical changes occurring in this disorder to explain the dominant symptom, the **“fish-smelling” vaginal discharge**. The principal change is in increased alkalinity of the vaginal milieu with elevation of pH. Many women with this disorder are asymptomatic, others may experience pruritus. **Risk factors** include intrauterine contraceptive devices (IUDs) and pregnancy but quite often no risk factors are apparent. Besides personal discomfort, the significance of bacterial vaginosis is in its **association with preterm delivery of low-birth-weight infants** (Hillier et al, 1995).

Cytology

The cervicovaginal smears in bacterial vaginosis show a characteristic **“dirty”** appearance, caused by presence of innumerable organisms, many covering the surfaces of squamous cells. The **“clue” cells**, caused by *G. vaginalis* and described above, are usually well evident, but other microorganisms, such as the comma-shaped *Mobiluncus* species may also aggregate on cell surfaces. Clearly, the value of the cervicovaginal smear in the diagnosis of bacterial vaginosis is limited. Schnadig et al (1989) aptly referred to this disorder as “clues, commas, and confusion.” The treatment must be based on clinical and bacteriologic data.

Tuberculosis

Tuberculosis of the female genital tract is, as a general rule, a **manifestation of disseminated disease**. There is no evidence that the genital tract can be the primary portal of entry. The most common manifestations of genital tuberculosis are tuberculous **salpingitis** and **endometritis**, but occasionally, though rarely in the Western world, the infection may involve the **uterine cervix** and, exceptionally, the vagina (Sutherland, 1985). The onset of AIDS has contributed to a marked increase in pulmonary tuberculosis, but so far there is no evidence that this has led to an increase in genital tuberculosis. The acid-fast mycobacterium tuberculosis cannot be identified in Papanicolaou stain. However, the presence of **tuberculous granulomas** can be occasionally recognized in cytologic preparations. As described in Chapters 19 and 31, the granulomas are nodular structures composed of modified macrophages resembling epithelial cells (**epithelioid cells**) and **multinucleated giant cells** with nuclei arranged at the periphery (**Langhans' cells**). A central area of necrosis (so-called **caseous necrosis**) is often present in the center of the granulomas.

Cytology

The smear pattern is that of chronic inflammation, wherein the epithelioid cells and Langhans' cells can sometimes be recognized. The epithelioid cells **have the approximate size of endocervical cells, are elongated, often carrot-shaped, pale-staining, eosinophilic, or cyanophilic cells with single round or oval finely stippled nuclei, occasionally containing small nucleoli**. The cytoplasm is usually finely vacuolated. The epithelioid cells sometimes form **approximately spherical clusters**, corresponding to the tubercles. Single epithelioid cells are difficult to identify in contrast to the large **Langhans'-type giant cells with peripheral nuclei** (Fig. 10-22). Fragments of amorphous eosinophilic material, corresponding to the central necrotic portions of the tubercle, round out the picture. The cytologic presentation of pulmonary tuberculosis is discussed in Chapter 19.

Although a number of communications pertaining to tuberculosis of the uterine cervix have emphasized the descriptive aspects of the cytologic presentation, the diagnosis is not easy. The identification of epithelioid cells in cervical and vaginal smears is difficult, and the

differentiation of Langhans' cells from other forms of the common multinucleated macrophages is very difficult for all practical intents and purposes. It would be particularly **inadvisable to suspect any woman with multinucleated macrophages in smears of harboring tuberculosis**. Thus, although the disease is still fairly common in the developing countries, in the industrialized countries it will remain a cytologic curiosity with most diagnoses rendered retrospectively after the histologic or microbiologic diagnosis has been established. Baum et al (2001) documented that polymerase chain reaction (PCR) may be helpful in the diagnosis of this disease.

***Mycobacterium avium-intracellulare* Complex**

As a consequence of the infection with human immunodeficiency virus (**HIV**) and acquired immunodeficiency syndrome (**AIDS**), a large number of previously very rare opportunistic infections have come to light, among them the acid-fast *Mycobacterium avium* (summaries in Perfect, 1988 and Lifson et al, 1994). The bacterium may lead to the formation of granulomas, similar to those seen in tuberculosis,

P.265

but quite often the organisms are phagocytized by large macrophages with vacuolated cytoplasm that do not form any organized structures, hence the name of the complex (see Chap. 19). To our knowledge, this organism has not been observed in cervicovaginal smears but is discussed in Chapter 31.

Figure 10-22 Tuberculosis of the cervix (cervical smear). *A.* Sheet of epithelioid cells characterized by a pale, faintly vacuolated, elongated cytoplasm and round or oval nuclei. The latter are finely stippled and contain small nucleoli. *B.* Large multinucleated Langhans' giant cell with peripherally placed nuclei. (High magnification.) (Courtesy of Dr. K.A. Misch, London, UK; from Misch KA, et al. Tuberculosis of the cervix: Cytology as an aid to diagnosis. J Clin Pathol 29:313-316, 1976.)

Granuloma venereum (Granuloma inguinale)

This is a sexually transmitted disease affecting mainly the skin and subcutaneous tissue of external genitalia in both sexes. **Ulcerative lesions** may affect the penis, vagina and uterine cervix (Fig. 10-23A). The disease is caused by Gramnegative, **bacillary encapsulated bodies** (*Calymmatobacterium granulomatis*, or **Donovan bodies**) that may be numerous in the cytoplasm of large, vacuolated "foamy" macrophages. They are best seen in Gram stain under oil immersion. The bipolar bodies, measuring about 1 to 2 μm in length, have been compared

with tiny “closed safety pins” (Fig. 10-23B).

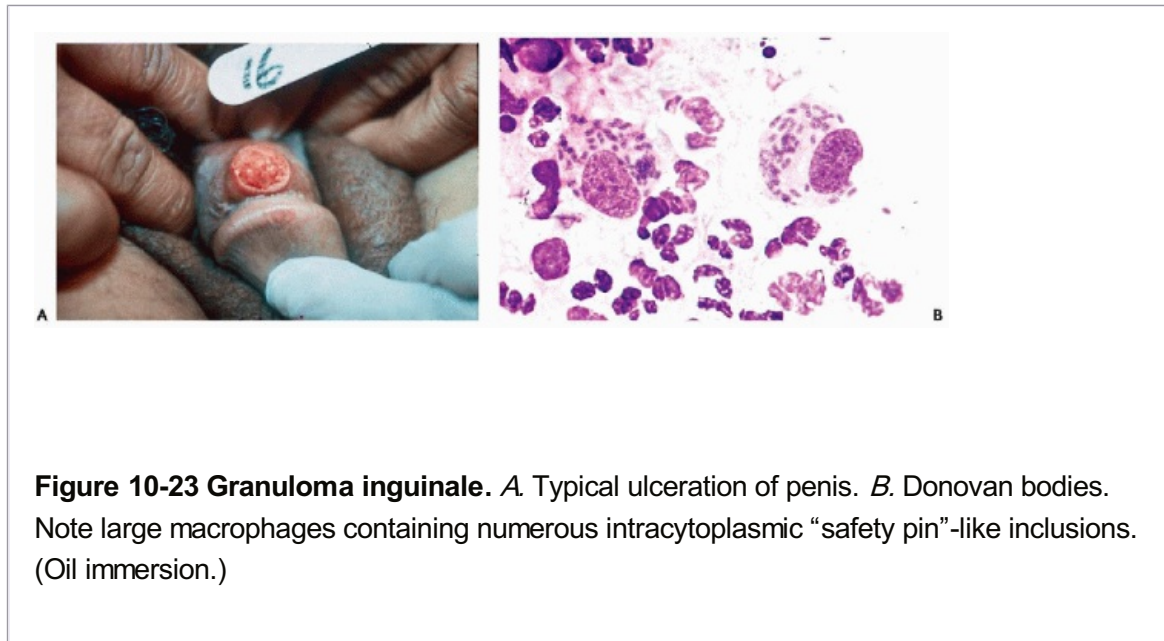

Figure 10-23 Granuloma inguinale. *A.* Typical ulceration of penis. *B.* Donovan bodies. Note large macrophages containing numerous intracytoplasmic “safety pin”-like inclusions. (Oil immersion.)

Actinomyces

This group of bacterial organisms that is sometimes difficult to classify on culture may be occasionally observed in the female genital tract. Gupta et al (1976) first pointed out the **association of this organism with the use of intrauterine contraceptive devices (IUDs)** and identified some of the organisms as *Actinomyces israeli*, which are known as human pathogens. In cervicovaginal smears, the organisms appear as a **central “ball” of basophilic filaments, with single, slender filaments spreading peripherally, sometimes surrounded by inflammatory exudate** (Fig. 10-24A,B). **Special stains, such as Brown and Brenn, may be required to document the club-shaped tips of the filaments** (Fig. 10-24C). **The finding of *Actinomyces* in cervicovaginal smears is a strong indication that the patient is a wearer of an IUD**, even if this history is not provided by the clinician.

Although in most instances, *Actinomyces* infection is harmless to the patient, there are several documented cases

P.266

of **pelvic inflammatory disease occurring mainly in women whose IUD has not been changed for 3 or more years**. These women can develop **pelvic abscesses** that may lead to sterility or even death of the patient (Fig. 10-24D). Subcutaneous abscesses may also occur, wherein the characteristic **“sulfur granules”** or grossly visible small yellow spheres of fungus, can be observed.

Figure 10-24 Actinomycosis in cervicovaginal smears. *A,B.* Colonies of actinomyces in a cervicovaginal smear from a woman who was a long-term IUD wearer. The colonies are composed of tangles of filaments which appear as bluish structures in the background of the smear. *C.* Structure of an actinomycotic deposit seen in Brown-Brenn stain. The clublike thickening of the periphery of the filaments is well seen. *D.* Tubo-ovarian abscess in a 49-year-old IUD wearer who had not changed her device for 13 years. The large colony of actinomyces surrounded by inflammatory reaction are shown.

An interesting rare finding in the differential diagnosis of actinomycosis was described in six patients by Bhagavan et al (1982). These are eosinophilic radiate structures, mimicking granules of *Actinomyces*, but composed of glycoproteins and lipids that may be calcified. The structures, which stain with Ziehl-Neelsen's stain for acid-fast organisms, were named **pseudoactinomycotic radiate granules** and were thought to represent a reaction to microorganisms or foreign bodies, repeatedly described in the past as the **Splendore-Hoeppli phenomenon**. It must be noted that only three of the six patients reported by Bhagavan were IUD users, and the granules were observed in tissues and not in smears.

For further discussion of cytologic findings in IUD wearers see above.

Leptothrix

There appears to be considerable controversy as to the identity of long, curving, filamentous organisms known as *Leptothrix vaginalis*. Rosebury (1962) identified two such organisms: a form of *Lactobacillus* (*Leptotrichia*) identical with *Leptothrix buccalis*, and a bacterium of the family of *Actinomyces* (*Bacterionema*), both of a similar morphologic appearance. According to Bibbo et al (1997), the *Actinomyces* type of organism is identifiable because of larger size and occasional branching. **Leptothrix is most commonly observed in conjunction with vaginal trichomoniasis** (see below). Bibbo et al (1997) observed this association in 95% of 1,300 consecutive genital smears with *Leptothrix*. Occasionally, association with fungi and other infectious agents was noted. The reason for this association is not known.

Chlamydia (Bedsonia)

These small, gram-negative microorganisms are the **agents of a variety of acute and chronic inflammatory disorders, such as inclusion conjunctivitis, trachoma, lymphogranuloma venereum, nonspecific urethritis, salpingitis, vaginitis, and cervicitis**. Screening of women for occult cervical **chlamydia** infection was shown as an effective means of prevention

P.267

of pelvic inflammatory disease (Scholes et al, 1996). The organisms are obligate intracellular parasites and are transmitted by personal contact. The first description of the cytologic presentation of this organism was by Naib (1970) in conjunctival smears of newborns and their mothers' genital tract. Gupta et al (1979) analyzed in considerable detail the cytologic presentation of the *Chlamydia* infection that can be observed in cervicovaginal smears. In the cytoplasm of squamous, metaplastic, and endocervical cells, the organism forms **tiny elementary coccoid bodies surrounded by narrow clear zones**. In the later stages of infection, the affected cells display one or more, sharply circumscribed, readily visible, **clear cytoplasmic vacuoles with a central acidophilic or basophilic inclusion—representing a condensation of the microorganisms** (Fig. 10-25A,B). Shiina (1985), in an elaborate study of inclusions in chlamydial infection, named the largest inclusions “**nebular inclusions**,” to differentiate them from smaller inclusions, a terminology also accepted by Henry et al (1993).

The cells containing *Chlamydia* may be somewhat atypical or multinucleated (Fig. 10-25C). Still, it must be stressed that **the presence of *Chlamydia* infection does not rule out the simultaneous presence of neoplastic lesions**. Patients with significant cellular abnormalities should have the benefit of further workup.

The original description of the morphologic manifestations of *Chlamydia* infection has been repeatedly challenged, notably by Shafer et al (1985), who compared the results of cytologic findings with culture of the microorganism. The presence of large vacuoles containing central inclusions (see Fig. 10-25B) could not be correlated with positive cultures. On the other hand, in several women with positive cultures, no cytologic abnormalities of the type described above could be observed. The unreliability of morphologic recognition of *Chlamydia* was also emphasized by Vinette-Leduc et al (1997).

Figure 10-25 Chlamydia infection. A. Small encapsulated primary bodies may be seen in the cytoplasm of the affected cell. B. Large cytoplasmic inclusion with an eosinophilic center (*arrow*). C. Multinucleated giant cell with several large cytoplasmic inclusions.

Because the infection with *Chlamydia trachomatis* is of major clinical significance, the consensus is that **the identification of this agent should always be confirmed by culture**, which also requires considerable care and optimal conditions for success (Kellog, 1989). Antibodies to *Chlamydia* have been developed. Fluorescence microscopy, using a labeled antibody, can be used as a screening procedure with a high degree of accuracy when compared with results of culture (Lindner et al, 1986). More recently, polymerase chain reaction, enzyme immunoassays, and ligase chain reaction using urine have been shown to be reliable in the diagnosis of this infection (Vinet-Leduc et al, 1997; Gaydos et al, 1998).

Chlamydia infection may also be associated with follicular cervicitis (see above).

Syphilis

This disease is caused by a sexually transmitted spirochete, *Treponema pallidum*. The disease which starts with an ulcerated localized lesion, the chancre, usually located on the genitalia, and subsequently becomes generalized, may cause inflammatory changes in the cervix that may mimic cervical cancer (Gutmann, 1995). The pattern of the **cervicovaginal smears** in Gutmann's cases showed only **nonspecific**

P.268

inflammation but the diagnosis could be established by the identification of the spirochetes in the granulomatous lesion in the biopsy.

Fungal Infections

***Candida glabrata* (Moniliasis)**

This family of fungal infections comprises two common organisms, *Candida albicans* and *Torulopsis glabrata* (jointly referred to as *monilia*). These are the most common pathogenic fungal agents observed in the female genital tract. Diabetes, pregnancy, and the use of antibacterial antibiotic agents that change the make-up of the vaginal flora are frequently associated with moniliasis. *Monilia* may also appear in patients with impaired leukocyte functions, in patients receiving immunosuppressive drugs and **may be the first manifestation of AIDS**. The infection may cause a **thick, milky vaginal discharge associated with intense itching and discomfort**.

Like most fungi of the family of Cryptococcaceae, *Candida albicans* and *Torulopsis glabrata* appear in two forms in smears: the **yeast form (conidia)** and the **fungus form (pseudohyphae)**. The **conidia** appear as **small, encapsulated, round, or oval organisms** (Fig. 10-26A). The capsule is inconspicuous. Budding may be noted in the form of smaller oval structures attached to one pole of the conidium. The **fungus form** is made up of long, thin filaments consisting of **elongated, bamboo-like spores**. **Usually, the spores are not surrounded by a capsule and, therefore, are designated as pseudohyphae** (see Fig. 10-26B).

Schnell and Voigt (1976) documented by electron microscopy that the fungus spores may be intracellular and located within the cytoplasm of squamous epithelial cells, wherein they can

also multiply.

Cytology

In spite of the intracytoplasmic penetration, the fungus does not appear to cause any serious injury to the epithelial lining of the cervix or the vagina but there may be complicating inflammatory phenomena. Neither the histologic nor the cytologic findings are specific or impressive. In the majority of cases, there are **no significant changes in smear patterns except for the presence of the fungus**. In other instances, there may be a mild inflammation affecting the squamous epithelium and the endocervix. **It must be stressed that secure identification of the fungi is usually not possible on the strength of morphologic examination alone.** Cultural and serologic data should be obtained for species diagnosis. Reports of cytologic atypias associated with this infection most likely reflect incidental abnormalities (Heller and Hoyt, 1971; Miguel et al, 1997).

Figure 10-26 Moniliasis. A. The budding yeast form of the fungus (*arrow*). B. Pseudohyphae.

Other Fungi

Occasionally, fungi other than *Candida* and *Torulopsis* are encountered in routine cytologic material. Their exact identification must rest on cultural characterization.

Coccidioidomycosis of the female genital tract has been reported (Saw et al, 1975). A case of *Paracoccidioides brasiliensis* was reported by Sheyn et al (2001). We also observed a case of **paracoccidioidomycosis** in the cervicovaginal smear of an asymptomatic 38-year-old woman. This fungus is mainly observed in Brazil and may cause pulmonary disease (see Chap. 19). The organism is spherical, brown, measuring from 10 to 60 μm in diameter, and is recognized by teardropshaped multiple buds resulting in the very characteristic “ship's wheel” appearance (Fig. 10-27A).

Cysts of *Toxoplasma* have been reported in cervicovaginal smears by Dominguez and Giron (1976), San Cristobal and Roset (1976), and Wasylenko et al (1991). A case of **blastomycosis**, identified in cervical smears, apparently transmitted to the patient from her husband with a prostatic infection, was reported by Dryer et al (1983).

We observed several examples of **Aspergillosis**, mainly in women wearing IUDs (Fig. 10-27B-D). In patients with AIDS, the fungus *Cryptococcus neoformans* may be observed, sometimes forming the unusual pseudohyphae rather than the common spherical spores with a

muroid capsule (Anandi et al, 1991). For further comments on this fungus, see Chapters 19 and 27. There are several additional published examples of uncommon fungus infections of the female genital tract, some cited in the bibliography. The clinical significance of these infections is uncertain and depends on whether the involvement of the genital tract is a

P.269

localized event or a manifestation of systemic disease, particularly in AIDS. The specific fungi are discussed again in several chapters, in reference to organs and organ systems where they are commonly encountered.

Figure 10-27 Various fungal infections. A. Paracoccidioidomycosis. The fungus is surrounded by spores that mimic a ship's steering wheel. B-D. Various forms of aspergillosis. B shows filaments and C and D fruiting heads of the fungus.

Viral Infections

Genital Herpes (Herpes Simplex Genitalis)

This is an important and common viral infection of the female genital tract, usually caused by **herpes simplex virus (HSV)** type II, whereas the perioral herpes (the common cold sores) is usually caused by HSV type I. The two types of herpesvirus cannot be distinguished morphologically but vary in their cultural and serologic characteristics. The frequency of the genital herpes varies according to the population studied from 0.09 to 0.9 per 1,000. Women in low socioeconomic brackets are more frequently affected than women from economically favored population groups. Jordan et al (1972) found a statistically significant increase in African Americans, when compared with American Indians, Hispanic Americans, and white women residents of the same region.

It was documented that nearly 40% of newly acquired HSV type II and two-thirds of HSV type I infections are asymptomatic (Langenberg et al, 1999). This observation has been first reported by cytology laboratories where the telltale cytologic evidence of herpesvirus infection has been observed in asymptomatic patients.

Clinically, **small vesicles** with clear content or, later, **superficial erosions** on the vulva or the penis characterize the genital herpes virus infection. The erosions may be painful. The vesicles are difficult to see in the vagina or on the cervix; however, the **erosions on the cervix may mimic cancer**. The disease is **chronic**, inasmuch as recurrences are common. It is generally thought that the virus **persists in ganglion cells** and becomes reactivated under a variety of circumstances. Obara et al (1997) were able to document the presence of viral DNA in human spinal ganglia by polymerase chain reaction (PCR) and in situ hybridization. A vaccine of moderate efficacy in women (but not in men) has been recently tested (Stanberry et al, 2002).

Histology

Regardless of viral type, the histologic and cytologic abnormalities of cells, characteristic of the common HSV infections are similar. The disease affects more commonly the squamous epithelium of the skin, vagina, and cervix than the endocervical epithelium.

On the skin and vulva, the disease begins as inflammatory nodules that lead to blister or vesicle formation by separation of layers of epidermis (Fig. 10-28). The center of the blister is filled with fluid. The epithelial cells lining

P.270

the blisters show changes characteristic of herpesvirus infection that are better seen in cytologic preparations.

Figure 10-28 Herpetic vesicle—skin. The presence of large intranuclear inclusions and multinucleated cells with degenerating dark nuclei is evident at the margin of the vesicle (*arrow*).

Figure 10-29 Herpesvirus infection. *A.* Early stage of viral infection. Enlarged and homogeneous “ground glass” nuclei in endocervical cells. *B.* A formation of a multinucleated giant cell with “ground glass” nuclei and nuclear molding. *C.* Multinucleated giant cells with “ground glass” nuclei and nuclear molding next to a cell with intranuclear viral inclusion. *D.* Higher magnification showing intranuclear viral inclusions forming in a multinucleated giant cell. The eosinophilic inclusions are surrounded by clear halo.

Cytology

The cytologic changes induced by herpesvirus are very characteristic and their identification in cervicovaginal smears is usually easy. In the **early stages of the disease, there is a moderate to marked nuclear enlargement in squamous or endocervical cells**, accompanied by a peculiar, faintly basophilic and opaque **homogenization of the nuclear contents, known as the “ground-glass” nuclei** (Fig. 10-29A). Occasionally, the homogenization is preceded or accompanied by nuclear vacuolization. This appearance of the nuclei is caused by an invasion of the nucleus by the virus, easily documented by electron microscopy. The herpes virions, composed of a capsule and a central electron-dense core, measure about 150 nm in diameter, are concentrated mainly in the nucleus, although cytoplasmic particles and membrane budding are a part of the picture. The virus causes **nuclear multiplication, resulting in crowding, and**

P.271

molding of the adjacent “ground-glass” nuclei, leading to the formation of multinucleated, often very large cells (occasionally well over 60 µm in diameter; Fig. 10-29B, C). The homogeneous inclusions **become condensed** and finally are localized in the center of the nuclei as **large eosinophilic inclusions**, significantly larger than any nucleolus. The inclusions are surrounded by a **clear area within the nucleoplasm** (Fig. 10-29D). Takeda (1969) documented the presence of herpes virions in the inclusions by electron microscopy. Experimental data (Teplitz et al, 1971) documented that intranuclear inclusions are a late event in the course of herpesvirus infection in vitro.

In the final stages of the infection, nuclear degeneration may set in, occasionally resulting in

formation of **bizarre, sometimes hyperchromatic nuclear masses due to nuclear fusion**. Occasionally, **pearl-like structures, imitating squamous carcinoma, may be observed** (Fig. 10-30). The identity of the bizarre cells in smears can be established by finding the characteristic ground-glass nuclei or nuclear inclusions in adjacent cells, or by use of additional techniques, described below. Ng et al (1970) proposed that certain morphologic differences may be observed between primary and recurrent herpetic infection. In the primary infection, there was a preponderance of multinucleated cells and few cells with eosinophilic inclusions; the opposite was observed for recurrent disease. Vesterinen et al (1977), in a careful study, failed to confirm Ng's findings and found no cytologic differences between primary and recurrent infections.

Figure 10-30 Cervical smears. Herpetic cervicitis. A few examples of exceptionally bizarre squamous cells resulting from infection with herpes simplex virus. *A*. Multinucleation. *B*. The huge degenerated nuclear mass undoubtedly represents the result of fusion of smaller nuclei that may still be observed in the two adjacent cells. *C*. Note the squamous pearl-like arrangement of cells. Elsewhere in these smears, clear-cut evidence of herpes was evident. (*A-C*, High magnification.) (Case courtesy of Dr. V. Palladino, Meadowbrook Hospital, East Meadow, NY.)

The **differential diagnosis of herpetic cervicitis** in cervicovaginal smears must include the very uncommon **trophoblastic syncytial cells** seen in pregnancy (see Chap. 8) and, in cases of extreme abnormalities, **squamous cancer**. In such cases, the absence of more classical

evidence of herpes is crucial in the differential diagnosis. In difficult cases, the morphologic suspicion of herpesvirus infection can be confirmed by **other techniques**. Stenkvist and Brege (1975) first applied **immunofluorescent techniques for the diagnosis of herpesvirus keratitis**, but the technique is also applicable to cervicovaginal smears. More recently, techniques of **in situ hybridization of viral DNA** (Tomita et al, 1991; Kobayashi et al, 1993), and **polymerase chain reaction** (Shibata, 1992; Slomka, 1998) have been applied to the diagnosis of this disease. Marshall et al (2001) reported that the results of the PCR techniques were more sensitive and took less time than viral culture.

It must be noted that **the presence of herpes does not rule out the presence of precancerous lesions or cancer of the uterine cervix**. In fact, we observed occasional cases where **the presence of herpes obscured and delayed the diagnosis of a cancerous lesion**. Longatto-Filho et al (1990)

P.272

noted the presence of herpetic infection in **smears of women after radiotherapy for cervical cancer**.

Genital herpesvirus infection in the woman has **important clinical implications**. The disease may be **transmitted to the fetus** during vaginal delivery with resulting disastrous infection resulting in major abnormalities (Florman et al, 1973). Type II herpesvirus has been implicated as a possible causative agent in carcinoma of the uterine cervix (see Chap. 11).

Cytomegalovirus

Cytomegalovirus is a virus of the **herpesvirus family**, so named because it forms very large inclusions in the affected cells. Even before the onset of AIDS, Morse et al (1974) recorded serologic evidence of **cytomegalovirus infection in the female genital tract** in women attending a venereal disease clinic. Surprisingly, the frequency of cytomegalovirus was similar to that of herpesvirus. Cytomegalovirus was associated in several instances with the presence of condylomata acuminata involving the vulva and sometimes the uterine cervix. The characteristic cytomegalic inclusions were, however, identified in smears of only 1 of 12 patients. Several observations of **cytomegalovirus in endocervical epithelium** are on record (Huang and Naylor, 1993; Henry-Stanley et al, 1993). Wenckebach and Curry (1976) observed three instances of cytomegalovirus infection in material from uterine curettage. In patients with AIDS, widespread cytomegalovirus infections are frequent and the **characteristic large intranuclear inclusions, accompanied by smaller satellite inclusions in the nucleus and the cytoplasm** may be observed in cervicovaginal smears. Hunt et al (1998) observed rod-shaped laminal satellite cytoplasmic inclusions. The reader will find further comments and illustrations in Chapters 19 and 22.

Herpesvirus of Unknown Type

We observed a case of herpesvirus infection in a cervicovaginal smear of a 31-year-old woman with AIDS. The virus caused **very large, homogeneous intranuclear inclusions** in squamous and endocervical cells (Fig. 10-31). Our initial impression was that the inclusions were of polyomavirus type but the electron microscopy of the viral inclusions was typical of a herpesvirus infection. The virions, filling the nuclei, had a typical core and capsule (Fig. 10-31C).

Dr. Yuan Chang of Columbia University College of Physicians and Surgeons, the discoverer of herpesvirus type VIII, examined some material from this patient and could not match it with any

known viruses of the herpes family. Unfortunately, the material was insufficient for sequencing of viral DNA and the type of the virus remains unknown at this time.

Other Viruses

Occasionally, *human polyomavirus*, which forms **homogeneous nuclear inclusions in urothelial cells**, commonly observed in the urinary sediment (discussed in detail in Chap. 22), has also been observed in vaginal smears, particularly during pregnancy (Wachtel, 1977).

Measles

The measles virus is usually transmitted among children but occasionally affects adults. The disease is characterized morphologically by hyperplasia of lymphoid tissues and by formation of **giant cells with numerous, up to 100, nuclei**, known as **Warthin-Finkeldey cells**. A case of measles cervicitis with these cells in smears and a molecular biologic confirmation of the disease were described by Heiman et al (1992).

Nonviral Inclusions

Occasionally, **eosinophilic cytoplasmic inclusions** may be observed in endocervical cells. These inclusions are of no diagnostic significance and closely resemble those observed in the bronchial cells (see Chap. 19) and in urothelial cells (see Chap. 22).

Parasitic Infections and Infestations

Trichomonas vaginalis

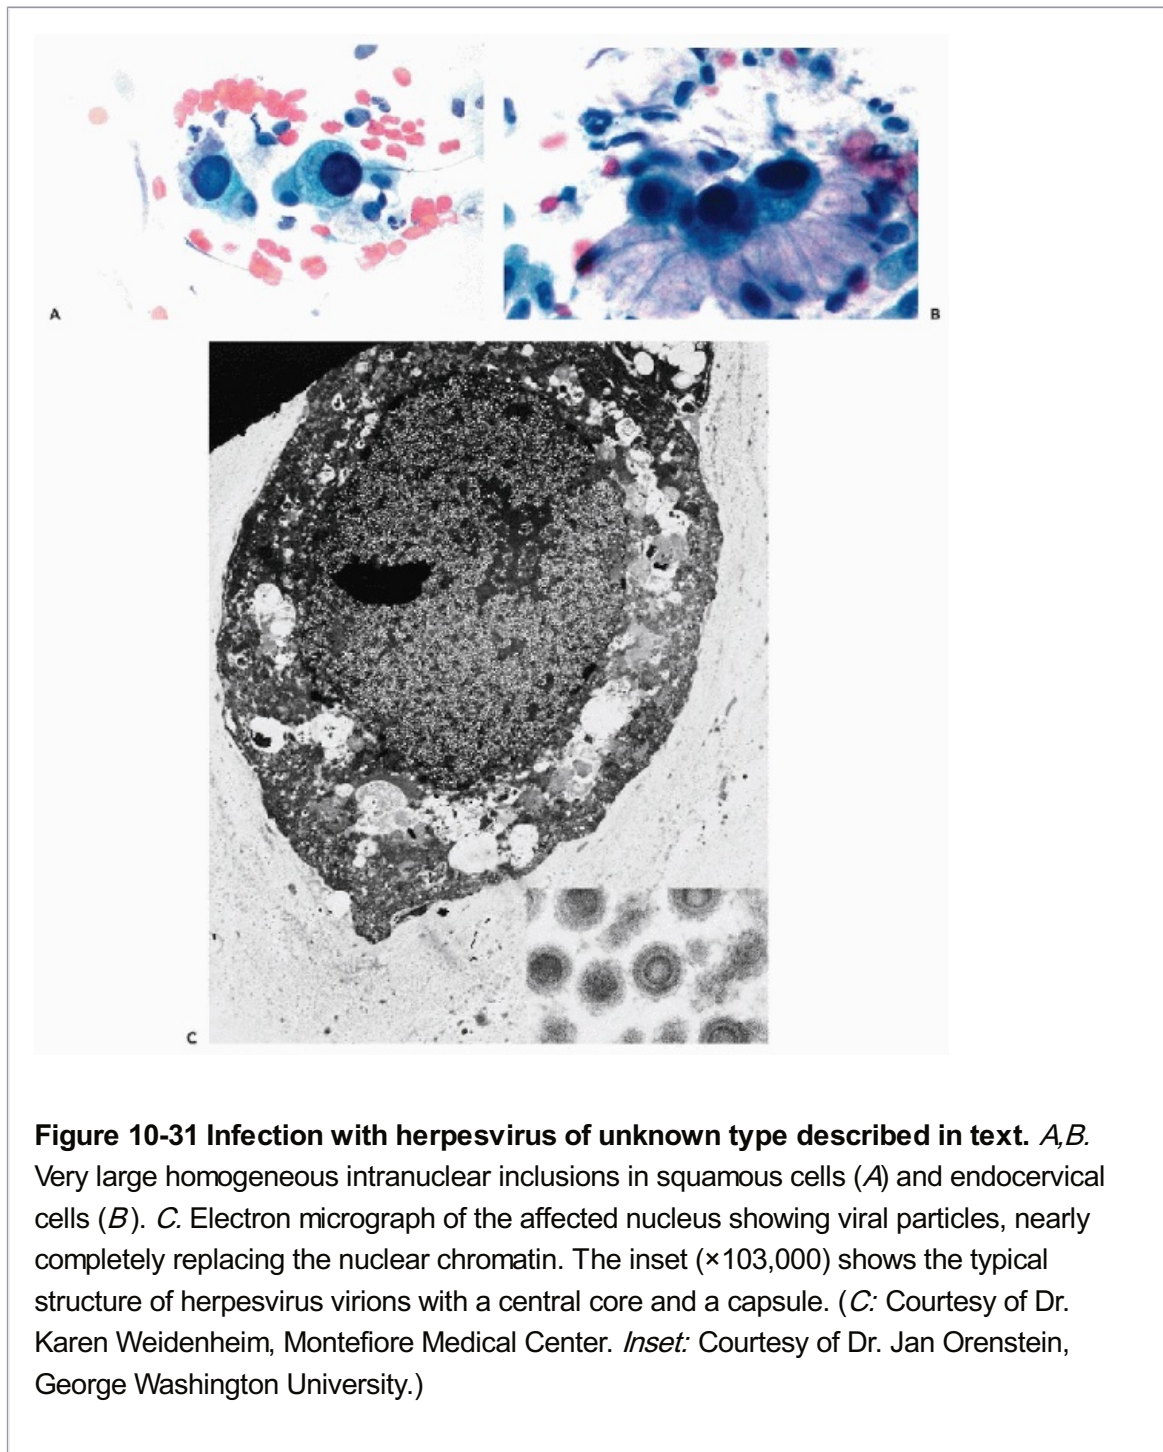

Infestation of the lower genital tract of the female with protozoon, *Trichomonas vaginalis*, is exceedingly common. Trussell (1947) estimated that at least 20% to 25% of adult women harbor the parasite and this estimate has not changed with the passage of time. It is generally accepted that **the male is the carrier of the parasite and that the infection is transmitted by sexual contact**. Gardner et al (1986) could document the presence of *Trichomonas* in the prostate by means of specific antisera. Kean and Wolinska (1956) have shown that *Trichomonas* frequently invades the urethra, which is thus a source of reinfection. Generally, patients with gynecologic symptoms, such as discharge or itching, have a higher incidence of infestation than do asymptomatic examinees. **The mere presence of *Trichomonas* in the genital tract of women is not synonymous with inflammation**. About 10% of infected women seem to suffer no ill effects from the presence of the parasite; however, an inflammatory process may occur in such patients with relative facility. The majority of women with inflammatory disease due to *Trichomonas* experience spontaneous healing and freedom of symptoms on repeated occasions. The exact mechanism that brings about the capricious clinical course of infestation with *Trichomonas* is not clear. The rise in the vaginal and cervical pH, just prior to and during the menstrual period, favors growth of the parasite. Experimental work by Weld and Kean (1956) suggests that tissue injury may be an important factor in survival of *Trichomonas vaginalis*.

Histology

Study of biopsies of the uterine cervix in the course of *Trichomonas* cervicitis suggests that the **parasite is capable of directly attacking the squamous epithelium**, which responds initially with **dilatation of capillary vessels** in epithelial papillae, followed by papillitis, edema, erosion of the superficial layers, and necrosis. The **“strawberry cervix”** observed clinically

corresponds to a marked distention of the superficial blood vessels and focal hemorrhages as seen in histologic material (see Fig. 10-13A).

P.273

P.274

Kolstad (1964), using colposcopy, confirmed the existence of a specific vascular pattern in the squamous epithelium of the cervix in *Trichomonas* infestation. Kolstad spoke of “**double-crested capillaries**,” which to his mind were diagnostic of the disease. The mechanisms of the interaction of *Trichomonas* with the squamous epithelium and the capillary vessels are unknown at the time of this writing.

Recognition

The identification of the parasite is essential before the diagnosis can be established with assurance and treatment instituted. The best way to recognize the parasite is the “**hanging drop**” technique in which a drop of vaginal secretions is placed on a slide and examined under the microscope. The flagellated parasites will be readily recognized as mobile structures rapidly criss-crossing the visual field. Wendel et al (2002) reported that culture and polymerase chain reaction in vaginal fluid have a higher sensitivity and specificity than “hanging drop” method in the recognition of the parasite. These methods, however, require a delay of several hours or days and add significantly to the cost.

In Papanicolaou-stained smears, the protozoa appear as **gray-green round or elliptical structures**, varying in size from 8 to 20 μm (Fig. 10-32A,B). Recognition of the **eccentrically located round nucleus** is helpful in the diagnosis. **Flagella**, in the form of filaments on one pole of the parasite, are seen only in well-preserved material. The parasite must be distinguished from particles of inspissated mucus and degenerating cellular material. Okuyama et al (1998) and Wendel et al (2002) identified the presence of ***Trichomonas* by polymerase chain reaction** in DNA obtained from cervicovaginal smears.

Figure 10-32 Trichomoniasis. *A.* The presence of gray-green parasites may be observed in the background of the inflammatory smear. *B.* High-power view of the parasite showing the typical graygreen tint and poorly preserved nuclei. The flagella cannot be seen in this preparation (see also Fig. 10-14C). *C.* Leptothrix. The filamentous bacterium commonly accompanies *Trichomonas* infestation. *D.* Synchronous infection with *Trichomonas* and *monilia*. Both organisms can be readily recognized in the smear.

The size of the *Trichomonas* organism is unrelated to its pathogenicity. Large *Trichomonas*, sometimes with multiple nuclei and flagella, appear when growth conditions are unfavorable; small sizes prevail when the growth conditions are favorable (D. Hollander, personal communication, 1976). Giant forms of this organism have been occasionally reported which are clearly a very rare event. **Filamentous bacteria of the genus *Leptothrix* are often found in smears in association with *Trichomonas*** (Fig. 10-32C). Synchronous infection with *Trichomonas* and *monilia* may be observed (Fig. 10-32D).

Cytology

As discussed above in the general description of inflammatory changes, Trichomoniasis is a prototype of cervicitis because it may induce changes in **smear pattern and cell**

P.275

configuration. Based on these features, an experienced observer may suggest *Trichomonas vaginalis* infestation, even if the parasite cannot be identified. Perhaps the most common change is **marked eosinophilia** observed in superficial, intermediate and larger parabasal squamous cells (see Fig. 10-14C). **Enlarged perinuclear clear zones or halos** in superficial cells are another common feature (see Fig. 10-16B). The halos surround the entire nucleus in a regular fashion and must be distinguished from the larger and asymmetrical clear zones of koilocytes, discussed in Chapter 11. In younger women with severe inflammatory reaction with necrosis of the superficial layers of the squamous epithelium, the smear may be dominated by parabasal cells, whereas in postmenopausal women, epithelial maturation can occur, presumably because of increased blood flow (see Fig. 10-15). However, it must be stressed that at least 20% of women, bearers of *Trichomonas*, have no symptoms whatever and the finding of the parasite in cervicovaginal smears is purely incidental.

Other changes that may be observed are nuclear pallor and enlargement, suggestive of **cell necrosis** (see Fig. 10-16A) and occasionally **apoptosis** (see Fig. 10-16C). Abnormalities of endocervical cells, such as cell enlargement, cytoplasmic vacuolization (see Fig. 10-17), presence of visible nucleoli and florid squamous metaplasia ("repair") may also occur.

Many years ago, some observers suggested that *Trichomonas* infestation may produce cytologic changes simulating cancer. This is most emphatically not the case. The question of whether patients with *Trichomonas* infestation are more prone to develop cervix cancer than other women has been answered in the negative (Koss and Wolinska, 1959). However, it should be emphasized that patients with all forms of cervix cancer, including carcinoma in situ, have a higher incidence of *Trichomonas* infestation than the normal population. Therefore, the presence of *Trichomonas* in a smear does not rule out the presence of a synchronous precancerous lesion or cancer of the uterine cervix.

Other Protozoa

Uncommon protozoa found in cervical smears include *Vorticella* [Hermann and Deininger (1963), San Cristobal et al (1976)] and *Entamoeba histolytica*. The latter, in the form of **cysts and trophozoites (amoebae)**, is seen predominantly in countries where amebic colitis is common. In Papanicolaou stain, the **trophozoites** are round or oval basophilic structures of variable sizes, averaging 15 to 20 µm in diameter but occasionally larger. The **nucleus** is usually eccentric, round, and provided with a central karyosome. The **cytoplasm** contains ingested red blood cells (**erythrophagocytosis**) (Fig. 10-33). Unless erythrocytes are identified, the diagnosis should be rendered with extreme caution. DeTorres and Benitez-Bribiesca (1973) suggested periodic acid-Schiff stain and acid-phosphatase stain for secure identification. These authors also point out that, in countries with high prevalence of amebiasis, the parasite may cause lesions of the vulva and cervix, clinically resembling carcinoma.

DeMoraes-Ruehsen et al (1980) described the presence of amebae, resembling *Entamoeba gingivalis*, in the genital tracts of users of **intrauterine contraceptive devices**.

Figure 10-33 Amebiasis. High magnification shows the organisms as a spherical structure with poorly preserved nuclei (arrow). Erythrophagocytosis is not evident. (Oil immersion.)

A case of **Chagas' disease** affecting the cervix was reported by Concetti et al (2000) in a woman with AIDS. The intracellular parasite, *Trypanosoma cruzi*, could be recognized in multinucleated giant cells, containing the characteristic reproductive form of the parasite, known as amastigotes. It is likely that this disorder will be observed in cervicovaginal smears in countries where the Chagas' disease is endemic, such as Peru.

The protozoan, *Balantidium coli*, is usually the cause of an intractable diarrhea. Several cases of balantidial vaginitis have been recorded (Berry, 1976). The **trophozoites** are very large (from 50 to 80 μm in length and from 40 to 60 μm in width) and are provided with a pellicle, bearing short cilia. At one end of the trophozoite, there is an indentation or a cytosome. A large nucleus is usually visible (Berry, 1976). A cyst form of the parasite has also been described. The identification of the large parasite in Papanicolaou stain is easy (Fig. 10-34).

Helminthic Infections (Worms)

Schistosomiasis (Bilharziasis)

Three important organisms cause diseases in humans: *Schistosoma haematobium*, *Schistosoma mansoni*, and *Schistosoma japonicum*. All three organisms are flukes, with a complex natural history, with man as the final host. Two of these, *S. haematobium* and *S. mansoni*, can affect the female genital tract. Freshwater snails are the intermediate host for these parasites. From the snails, the motile forms of the organisms, the **cercariae**, are released in water, penetrate human skin, causing "swimmers' itch," and establish themselves in various organs. *S. haematobium* usually lodges in lymphatics of the pelvic organs, mainly the urinary bladder, whereas *S. mansoni* establishes itself primarily in the liver and the lower gastrointestinal tract. The **cercariae become mature worms**. The female worms release the characteristic ova, whence larval forms (**miracidia**) hatch and are released into water in urine or feces. In suitable surroundings the miracidia find the intermediate host (snails) and the cycle recommences. For a detailed account of the life cycle of schistosomes, the reader is referred to

the book by Jordan and Webbe (1969)

P.276

and to the outstanding contributions by the late Anne Berry (1966, 1971, 1976).

Figure 10-34 *Balantidium coli*, vaginal smear. Very large trophozoite with ciliated pellicle. Note the large nucleus and, at the opposite pole, a cytosome. ($\times 600$.) (Photo courtesy of the late Dr. Ann V. Berry, Johannesburg, South Africa.)

S. haematobium is found principally in Africa, whereas ***S. mansoni*** is found in Africa, South America, and the Caribbean. As a consequence of jet-age movement of people across the continents, such infections may now be seen in all geographic locations. Both ***S. haematobium*** and ***S. mansoni*** may invade the lymphatics of the uterus and deposit ova in the stroma of the uterine cervix (Fig. 10-35A). Clinically, the lesions of the uterine cervix due to schistosomiasis may imitate cancer. The identification of the parasites is based on recognition of ova and larval stages (miracidia) in the cervicovaginal smears.

Figure 10-35 Parasites. *Schistosoma haematobium* in tissue (A) and in vaginal/cervical smear (B). The terminal spine of the ova is well seen. C. *Enterobius* (pin worm) ova. The typical polar operculum may be observed. D. *Filaria* (*Mansonella*) in a cervicovaginal smear.

In Papanicolaou-stained material, the **ova** of both species

P.277

have a **thick, semitranslucent shell provided with a spine**. The **spine is usually terminal in *S. haematobium*** and **lateral in *S. mansoni***. The ova average about 140 μm in length and 60 to 70 μm in width. Smaller and larger sizes may be observed (Fig. 10-35B).

Figure 10-36 Vaginal smears. Ovum of *Trichuris trichiura* (A) and ova of *Taenia* (B). (Photos courtesy of the late Dr. Ann V. Berry, Johannesburg, South Africa.)

The **miracidia are boat-shaped organisms**, that in general configuration, resemble the ova, except for the absence of the shell. The miracidia may show active movement and, therefore, may show variable shapes and sizes. For the detail of anatomy of the miracidia, the reader is referred to Berry's papers. The **smear background in schistosomiasis** usually shows

purulent exudate with an admixture of **eosinophilic leukocytes**, a common component of tissue reactions to parasites.

Intestinal Parasites: Nematodes (Roundworms) and Cestodes (Tapeworms)

Ova of various intestinal parasites may be observed in vaginal and cervical smears (Berry, 1976). It must be stressed that while these findings are uncommon in the developed countries, they are frequent in the developing countries. **Ova of *Enterobius vermicularis* (pinworm)** are perhaps the most frequent finding: the ova measure about $50 \times 25 \mu\text{m}$, stain yellow in Papanicolaou stain, and have a refringent, translucent, thick membrane, one edge of which is folded. A larva may be observed within the ovum (Fig. 10-35C). Occasionally, free larvae have been observed (San Cristobal and DeMundi, 1976).

In tropical countries, ***Trichuris trichiura* (whipworm)** may be observed. The brown ova are of approximately the same size as those of *Enterobius* but are provided with a translucent knob on both poles (Fig. 10-36A). There is so far no record of ova of ***Ascaris lumbricoides*** in genital smears.

Figure 10-37 *Filaria (Onchocerca volvulus)* in vaginal smears. (Oil immersion.)
(Courtesy of Dr. Rosa de Borges, Caracas, Venezuela.)

The flat worms, ***Taenia solium*, *Taenia saginata*, and *Taenia echinococcus***, also play a role in diagnostic cytology. The round, brown eggs, about $35 \mu\text{m}$ in diameter, have a radially striated shell and have been observed in smears from the female genital tract (Fig. 10-36B). The reader is referred to Chapters 19, 25, and 29 for further comments on echinococcosis.

Strongyloides stercoralis, another intestinal parasite, usually observed in pulmonary specimens, has been observed in a cervicovaginal smear by Murty et al (1994). For a full description of this parasite and its life cycle see Chapter 19.

Filariae

The extent of worldwide spread of various forms of filariasis is enormous. For the most part, the tiny, **thread-like worms** invade humans through insect bites, multiply in blood, and then settle in various organs, often blocking lymphatics of subcutaneous tissue. For the fine points of morphologic differential diagnosis among the various species and for the geographic

distribution of filariae, the reader is referred to other sources (e.g., Ash and Spitz *Atlas*, 1945).

There are several recorded instances of various species of filariae observed in the smears from the female genital tract: *Wuchereria bancrofti* (Chandra et al, 1975), *Onchocerca volvulus* (DeBorges, 1971), and *Dipetalonema perstans* (Sharma et al, 1971). All filariae share the slender worm-like appearance with filiform end and measure from 1 to 4 cm in length (see Figs. 10-35D and 10-37).

P.278

Arthropods (Insects)

Occasionally arthropods, such as water fleas or mites, or parts thereof, may be observed in vaginal smears. Bechtold et al (1952) pointed out that **carpet beetle hairs**, resembling serrated brown arrows, are a fairly common finding (see Chap. 8).

Squamous Carcinoma of the Uterine Cervix and Its Precursors

P.283

NATURAL HISTORY, EPIDEMIOLOGY, ETIOLOGY, AND PATHOGENESIS

Carcinoma of the uterine cervix and its precursors belong to the best studied forms of human cancer. In this chapter, only cancers and precancerous lesions with the origin in, or characteristics of, squamous epithelium will be discussed. The term **squamous carcinoma** has been in general use to describe these lesions. The alternate term **epidermoid carcinoma** will be used to describe lesions with limited formation of keratin. **Adenocarcinomas** and related lesions are discussed in Chapter 12.

It has been repeatedly documented that invasive carcinoma of the uterine cervix, regardless of type, **develops from precursor lesions or abnormal surface epithelium**, which, in its classic form, is known as **carcinoma in situ** (International Stage 0). The precursor lesions do not produce any specific alterations of the cervix visible to the naked eye. Therefore, before the introduction of cervicovaginal cytology and colposcopy, these lesions were a rarity and their discovery was incidental in biopsies of the cervix and in hysterectomy specimens. Since the introduction of mass screening by smears, and with accumulated experience, it has been shown that these lesions are quite common. The investigations of the precursor lesions is facilitated by the accessibility of the cervix to clinical examination and inspection by the colposcope and the ease of cytologic and histologic sampling that could be subjected, not only to microscopic scrutiny, but also to cytogenetic and molecular biologic analysis. Although considerable progress has been made in the understanding of the natural history of these lesions, there are still many areas of ignorance requiring further clarification.

The assumption of **the prevention programs of cancer of the uterine cervix** is that **the precursor lesions may be identified in cervicovaginal preparations and eradicated, thus preventing the occurrence of invasive cancer**. The success of these programs has been confirmed because, over the past half century, the rate of invasive cancer of the uterine cervix has been reduced by about 70% in the United States and other developed countries (summaries in Koss, 1989; Cannistra and Niloff, 1996). In developing countries, however, cancer of the cervix remains a common disease with a high mortality rate.

The first part of the chapter is devoted to epidemiology, etiology, pathogenesis, and natural history of precursor lesions and squamous cancer of the uterine cervix. The cytology and histopathology of these lesions are discussed in Part 2.

HISTORICAL PERSPECTIVE

The identification of invasive carcinoma of the uterine cervix as a distinct disease, different from other tumors of the uterus, was significantly enhanced with the introduction of uterine biopsies by Ruge and Veit in 1877. The histologic features of invasive squamous cancer were well known toward the end of the 19th century and were illustrated in a number of textbooks, such as that by Amann, published in 1897. In fact, Amann also recognized the component cells of squamous carcinoma (Fig. 11-1) but neither he nor his contemporaries addressed the issue of the origin of invasive cancer. The credit for this contribution goes to W. Schauenstein, a gynecologist from Graz, Austria, who published, in 1908, a remarkable paper pointing out the striking similarity between the histologic patterns of cancerous surface

P.284

epithelium (Krebsbelag in the original German) and superficially infiltrating squamous cancer of the cervix. He expressed the opinion that the abnormal surface epithelium deserved the name of cancer because it was the source of origin of infiltrating carcinoma (Fig. 11-2).

Figure 11-1 Facsimile of drawings of a cervical carcinoma and cancer cells, derived from Amann's book on gynecologic histology, which appeared in 1897. The tissue lesion that was diagnosed as "carcinoma of cervix originating from squamous epithelium" would undoubtedly be classified today as a carcinoma in situ with extension to endocervical glands. Note the remarkably accurate drawings of "pyknotic cancer cells." (JF Bergman, publisher, Wiesbaden, Germany.)

Pronai in 1909 and Rubin in 1910 supported Schauenstein's observations by additional examples. The matter was also dealt with in considerable detail in a large book by Schottländer and Kermauner, published in 1912, which contains a detailed analysis of several hundred cases of uterine cancer. In reference to cancer of the uterine cervix, Schottländer and Kermauner coined the term **carcinoma in situ** to describe the cancerous epithelium on the surface of the uterine cervix and considered this lesion to be malignant. Although, in the American literature, the term "carcinoma in situ" is often attributed to the pathologist A.C. Broders of the Mayo Clinic, who published a paper on this topic in 1932, he was not the first person to use this term. Numerous synonyms, such as **preinvasive carcinoma, intraepithelial carcinoma, precancerous epithelium, Bowen's disease of the cervix, and squamous or epidermoid carcinoma without evidence of invasion**, have been used intermittently in the literature for many years to describe and discuss this lesion. The critical issue of whether such epithelial abnormalities may be recognized as cancerous in the absence of an invasive component was the subject of numerous controversies in the first decades of the 20th century, first addressed by Rubin in 1910. In the 1920s and 1930s, two German gynecologic pathologists, Walter Schiller and Robert Meyer (both of whom escaped to the United States to avoid Hitler's racial laws) wrote extensively on the subject of interpretation of cervical biopsies and concluded that precancerous intraepithelial lesions were indeed precursors of invasive cervical cancer and could be so identified under the microscope. Still, **because the behavior of the precancerous lesions has been shown to be unpredictable** and not necessarily leading to invasive cancer, the controversy was not put to rest. With the onset of the 21st century, there are few observers who use the term "carcinoma in situ." Most of them favor other terms, such as **dysplasia, cervical intraepithelial neoplasia (CIN), and squamous intraepithelial lesions (SIL) of low (LGSIL) and high-grade (HGSIL)**, to be defined and discussed below.

Figure 11-2 Facsimile of a drawing from the paper of Schauenstein, published in 1908, which served as a basis for his statement that the various forms of cervical cancer “show only quantitative and not qualitative differences.” The two lesions on the left are carcinomas in situ. (From Arch Gynaecol 85:576-616, 1908.)

In 1925, a German gynecologist, Hinselmann, realized that the naked eye was not sufficiently keen to detect inconspicuous alterations of the cervical epithelium caused by early cancer and devised a magnifying instrument—the **colposcope**—that allowed the inspection of the **vascular changes on the surface of the cervix** at magnifications up to 20 times. Hinselmann supplemented the colposcopic investigation with cervical biopsies. As related by Limburg (1956), Hinselmann had much difficulty in trying to convince the conservative German pathologists that the precursor

P.285

lesions discovered by colposcopy were malignant. To avoid controversies he devised a system of classification of the lesions into four groups (**Rubriks**), thus avoiding the term cancer. Unfortunately, the **Rubriks** included a variety of findings ranging from simple metaplasias to carcinomas in situ; thus, this method of classification has not found much following. The **Rubriks** are reminiscent of Papanicolaou's “**Classes**,” a system of diagnosis applied to cervicovaginal smears many years later and discussed below.

In trained hands, the colposcope proved to be a very useful instrument, which has been extensively used in Europe and, with a delay of several decades, has also been adopted in the United States. It is of historical interest that the resistance to colposcopy in the United States was based on the notion that “no American woman will stay still long enough to be colposcoped,” as related to me many years ago by a senior gynecologist. The principal current **application of colposcopy is in the localization and biopsies of epithelial abnormalities detected by cytology.**

The introduction of **cervicovaginal cytology**, as a means of detection of precancerous lesions of the uterine cervix, has been another milestone in the study of cancer of the uterine cervix (Babès, 1928; Papanicolaou, 1928; Viana, 1928). The method has played a central role as a tool of prevention of cervix cancer. As narrated in Chapter 1 of this book, Dr. George N. Papanicolaou's name is synonymous with the cytologic method of cervix cancer diagnosis and detection, and his contributions have been honored by the common term, **Pap smear**. Events leading to the recognition of **human papillomavirus (HPV)** as an important factor in the genesis of cancer of the uterine cervix are described below.

EPIDEMIOLOGY

In 1842, an Italian physician, Rigoni-Stern, examined the death records of the city of Verona for the years 1760 to 1839 and pointed out that **cancer of the uterus was much more frequent among married women and widows than among unmarried women and nuns**. He made a number of other fundamental observations and is considered to be the father of cancer

epidemiology. The term **cancer of the uterus**, used by Rigoni-Stern, undoubtedly comprised a large proportion of cancers of the uterine cervix, which was then, and remained for another century, by far the most common malignant disease of the uterus until the cancer detection systems took hold in the 1960s. Rigoni-Stern's paper appears to be the first recorded reference to what has been subsequently termed "**marital**" or "**sexual**" **events** that play a major role in epidemiology of squamous carcinoma of the cervix. Two epidemiologic factors play a major role in the genesis of this disease. These are:

- **Young age at first intercourse**
- **Promiscuity or multiplicity of sexual partners**

It has been documented that women who begin their sexual life in their teens, who have multiple sexual partners, or who are multiparous at an early age, are at a greater risk for cancer of the cervix than women who begin their sexual activity later in life and are monogamous or have only few partners. This disease is extremely rare among nuns but common among prostitutes (Dunn, 1953; Wynder, 1954; Towne, 1955; Kaiser and Gilliam, 1958; Taylor et al, 1959; Pereira, 1961; Roitkin, 1962, 1973; Nix, 1964; Christopherson and Parker, 1965; Martin, 1967; Barron and Richart, 1971; Kessler et al, 1974). Pridan and Lilienfeld (1971) pointed out that, although cancer of the uterine cervix is rare among Jewish women, it may be observed either in promiscuous women or women whose *husbands* were promiscuous. As briefly discussed in Chapter 10, women using intrauterine contraceptive devices or hormonal contraception are at a higher risk for development of cervical cancer precursors than women using the diaphragm, or whose partners use condoms, again suggesting that a direct contact between the sexes is a factor in carcinoma of the cervix. **Thus, the pattern of occurrence of carcinoma of the uterine cervix is, in many ways, similar to that of a sexually transmitted disease, suggesting that a sex-related transfer of a factor or factors triggers the cancerous events.**

RISK FACTORS

Sexually Transmitted Diseases

A great many sexually transmitted disease agents were, at one time or another, considered as possible triggers of cancer of the cervix, including **syphilis** (Levin et al, 1942) and ***Trichomonas vaginalis*** (De Carnieri and DiRe, 1970). With effective treatment of syphilis by antibiotics, this disease ceased to be considered to be a suspect agent. In an extensive study, Koss and Wolinska (1959) ruled out Trichomoniasis as a candidate agent. Association of subtypes of ***Chlamydia trachomatis*** with cervical squamous carcinoma was discussed as a possible risk factor by Antilla et al (2001).

Spermatozoa, Smegma, and Cigarette Smoking

In 1968, Coppleson and Reid proposed that **spermatozoa** may penetrate the endocervical cells, change their genetic make-up (genome), and thus trigger cancerous proliferation. This theory received little attention until further observations by Bendich et al (1974, 1976) and by Higgins (1975), who pointed out that **mammalian spermatozoa** may indeed penetrate cultured mammalian cells in vitro and significantly **modify their morphology, growth characteristics, and genome**. Thus, this suggestion, which has been revived again in a paper by Singer et al (1976), is deserving of further investigation.

The role of **smegma** as a possible carcinogenic agent was linked to the absence of circumcision in marital partners of women developing cervical cancer. There is no objective supportive evidence that this theory is valid, as summarized by Terris et al (1973).

Several epidemiologic studies pointed out that **cigarette smoking** is a possible risk factor in cancer of the cervix

P.286

(Leyde and Broste, 1989; Slattery et al, 1989; Cocker et al, 1992; Daling et al, 1996). The finding of metabolites of tobacco carcinogens in cervical mucus (Philips et al, 1990; Prokopczyk et al, 1997) suggests that the relationship does not only pertain to lifestyle but may, in fact, have a biochemical basis. DNA damage in cervical epithelium related to tobacco carcinogens has been reported (Simons et al, 1995). Ho et al (1998) observed some synchrony between cigarette smoking, human papillomavirus type 16, and the occurrence of high-grade precursor lesions of the uterine cervix.

Immune deficiencies, as a consequence of infection with human immunodeficiency virus (HIV), acquired immunodeficiency syndrome (AIDS), immunosuppression after organ transplant or chemotherapy for cancer, are also risk factors for cervix cancer, to be discussed below in reference to human papillomavirus infection.

VIRAL AGENTS

During the last 30 years of the 20th century, several sexually transmitted viruses were considered as possible agents involved in the genesis of cancer of the uterine cervix. The two most important agents are herpesvirus type 2 and human papillomavirus (HPV).

Herpesvirus Type 2 (HSV-2)

The proponents of the HSV-2, a variant of herpesvirus discussed in Chapter 10, as the transmissible biologic agent triggering carcinoma of the uterine cervix, pointed out that the virus is sexually transmitted and ubiquitous and that women with antibodies to HSV-2 have a higher incidence of precancerous lesions of the cervix than controls (Adam et al, 1971; Nahmias et al, 1974). Aurelian et al (1971) isolated the virus from cervical cancer cells grown in vitro. The expression of the viral genome could be demonstrated in cervical cancer cells by immunofluorescence (Aurelian, 1974). Centifano et al (1972) demonstrated the virus in the male genitourinary tract, a possible source of infection. Wentz et al (1975) produced carcinoma of the cervix in mice with HSV-2.

The studies of antibodies to HSV-2 in various population groups, which first suggested a relationship of this virus to carcinoma of the cervix, were not consistent. In a review of this evidence, Kessler (1974) pointed out that the serologic methods used by the various investigators were quite variable and may have accounted for the observed differences. Subsequent studies, notably a much cited paper by Vonka et al (1984), failed to confirm the differences in serologic positivity between women with and without precancerous lesions or cancer of the uterine cervix. At the time of this writing (2004), there is little enthusiasm for the role of HSV-2 as a causative factor of cancer of the uterine cervix. On the other hand, the possibility that HSV-2 infection plays an indirect role in the pathogenesis of these lesions as a co-factor in human papillomavirus infection has been suggested (zur Hausen, 1982; Daling et al, 1996).

Human Papillomaviruses (HPVs)

In 1933, Shope and Hurst demonstrated that skin papillomas in wild cottontail rabbits could be transmitted from animal to animal by a cell-free extract, leading to the assumption that this disease was caused by a virus. The domestic rabbit was generally resistant to this infection, although, in some animals, the infection produced skin cancer (Rous and Beard, 1935). In 1940, Rous and Kidd documented that the virus (by then named **papillomavirus**) could produce invasive and metastatic skin cancers in domestic rabbits pretreated with tar. Thus, the **Shope papillomavirus was thought to be a co-carcinogenic agent, usually requiring the presence of another initiating agent, to produce a malignant tumor** in a species of animals other than the species of origin.

Many animal papillomaviruses are known today; they are generally species-specific and usually produce **benign lesions of the skin or subcutaneous tissues**. The bovine papillomavirus is thought to be a contributory factor in bladder tumors in cows.

In reference to the uterine cervix, the occurrence of invasive cancer (Hisaw and Hisaw, 1958) and of carcinoma in situ and related precancerous lesions in monkeys (*Macaca* species) was reported (Sternberg, 1961; Hertig et al, 1983). One such lesion is illustrated in Figure 11-3. It is of interest, therefore, that **papillomavirus type RhPV-1 has been observed in penile and cervix cancers in rhesus monkeys** (Kloster et al, 1988; Ostrow et al, 1995). Summaries of studies on animal papillomaviruses may be found in a contribution by Sundberg (1987) and in the IARC (International Association for Research on Cancer) monograph on Human Papillomaviruses (1995).

Early Observations in Humans

Human papillomaviruses (HPVs or "**wart viruses**") have been suspected for many years as the cause of ordinary **skin warts** and of the common wart-like skin lesions known as **venereal warts** or **condylomata acuminata**, often simply designated as "**condylomas**." *Condylomata acuminata* generally occur on external genitalia, the perineum, and the

P.287

perianal region (the latter most commonly seen in homosexual males, but, occasionally, also observed in women and children), where they form multiple, pedunculated or sessile, cauliflower-like excrescences surfaced by thick folds of squamous epithelium (Fig. 11-4); such lesions may also occur in the vagina and, rarely, on the uterine cervix. Similar flat, moist lesions, known as **condylomata lata**, occurring on external genitalia, are associated with secondary syphilis.

Figure 11-3 Carcinoma in situ observed in the cervix of a monkey, *Macaca mulatta*. (From Sternberg SS. In situ carcinoma of the cervix in a monkey [*Macaca mulatta*]. Am J Obstet Gynecol 82: 96-98, 1961.)

The viral origin of *condylomata acuminata* received strong additional support when **viral particles were observed in the nuclei of squamous epithelial cells** by electron microscopy (Dunn and Ogilvie, 1968; Oriel and Alameida, 1970). Studies of veterans returning from the Korean War, and of their spouses, have shown that *condylomata acuminata* is a sexually transmitted disease that takes several months to develop (Oriel, 1971). This was the first evidence that **HPVs can cause a disease in humans**.

In 1956, Koss and Durfee coined the term **kilocytotic atypia** (from Greek, *koiros* = a hollow and *kytos* = cell) to describe, in cervicovaginal smears, peculiar **large squamous cells with enlarged, hyperchromatic nuclei and a large clear perinuclear clear zone or halo, known today as koilocytes** (see Fig. 11-6D). It has been shown subsequently, by electron microscopy, that the nuclei of koilocytes contain mature viral particles, whereas the **clear cytoplasmic zones (halos) represent a collapse of the cytoplasmic filaments or cytoplasmic necrosis** (see Fig. 11-6A) caused by the viral infection (Shokri Tabibzadeh et al, 1981; Meisels et al, 1983, 1984). For a detailed analysis of koilocytes in cervicovaginal cytologic material, see Part 2 of this chapter. The presence of these cells in smears was shown by Koss and Durfee to **correlate with histologic abnormalities of squamous epithelium resembling skin warts and, hence, named “warty lesions”** (see Fig. 11-4B). An association of koilocytes, or warty lesions with bona fide carcinoma in situ, was observed in 18 of 40 cases and in 9 of 53 invasive carcinomas. Koilocytes were also observed in two “squamous papillomas” of the cervix that today would be classified as condylomas.

Such cells were previously described in 1949 and in several subsequent publications by a major contributor to cervical cytology, J. Ernest Ayre, who variously named them “**precancer cell complex,**” “**halo cells,**” or “**nearocarcinoma**” (early cancer). In a very few poorly documented anecdotal cases, Ayre reported a progression of this cytologic pattern to carcinoma of the cervix. **In 1960, Ayre proposed that the “halo cells” may be caused by a not further defined viral infection.**

Figure 11-4 Condylomata. Condyloma of anus (A) and of the vulva (B). For detailed description of structure, see text. Note epithelial folds in A.

In December 1976 and January 1977, Meisels and Fortin, from Canada, and Purola and Savia, from Finland, simultaneously published papers linking condylomas and similar precancerous lesions of the uterine cervix with “wart virus” (since renamed **human papillomavirus or HPV**). The **common denominator of these lesions** was the presence of “**halo cells**” or **koilocytes**. The first confirmations of the association of some precancerous lesions of the uterine cervix with a viral infection were published in 1978 by Laverly et al from Australia and in 1979 by Torre et al from Italy, who observed, by electron microscopy, viral particles consistent with a papillomavirus in precancerous cervical lesions.

In a critically important paper, Kreider et al (1985) reported the induction of koilocytosis in fragments of normal human squamous epithelium by HPV type 11 in nude mice, thus confirming the role of HPV in the formation of this cell alteration. Subsequently, the presence of viruses of the papillomavirus family in precancerous lesions and invasive cancer of the uterine cervix was confirmed by a variety of techniques (see below).

The initial cytologic, histologic, and clinical studies confirmed that **the presence of koilocytes and, hence, HPV infection, was common in women with precancerous lesions of the uterine cervix, particularly in bearers of flat, wart-like lesions, soon renamed “flat condylomas”** (Purola and Savia, 1977; Meisels and Morin, 1983). In young women, age 20 or less, nearly all precancerous cervical lesions had a morphologic configuration suggestive of HPV infection (Syrjänen, 1979). In subsequent years, these studies were significantly expanded, confirming the relationship between the precancerous lesions and manifestations of HPV infection in thousands of women.

It was also reported in the first edition of this book in

P.288

1961 (and in subsequent editions), that **the cytologic features of the uncommon large condylomas on the surface of the uterine cervix in very young women show marked similarities with precursor lesions of cervical cancer**. For description of these findings, see Part 2 of this chapter.

Subsequently, other minor cytologic abnormalities, such as parakeratosis, formation of **squamous “pearls,” binucleation, slight enlargement of nuclei in squamous cells, and karyorrhexis** were also considered as secondary landmarks of HPV infection. These abnormalities are discussed in Chapter 10. In the experience of this writer, these changes are not specific and may occur under a variety of circumstances, not necessarily related to HPV infection, in agreement with Tanaka et al (1993).

Molecular Biology

While the initial morphologic observations were being pieced together, substantial work was going on in several laboratories of molecular virology to identify and characterize papillomaviruses and clarify their role as possible oncogenic agents. Unfortunately, HPVs are very finicky and, so far, there is no tissue culture system to support their growth in vitro. Hence, the initial evidence had to be gathered by molecular cloning of viral DNA in plasmids and by Southern type analysis of viral DNA (Gissmann and zur Hausen, 1976; zur Hausen, 1976). For description of the plasmid technique and of the Southern blot analysis, see Chapter 3. These studies led to the identification of a few common types of HPVs (6, 11, and 16) and their fundamental structure.

Figure 11-5 Structure of HPV. The drawing shows double-stranded DNA composed of

approximately 7,900 nucleotides (center ring) and the position of open reading frames (ORFs) E1-E7 and L1 and L2 (outer rings). The function of the reading frames is discussed in text. (Courtesy of Dr. Robert Burk, Albert Einstein College of Medicine, Bronx, NY.)

The HPVs are **small, circular, double-stranded DNA viruses, each strand being composed of approximately 7,900 nucleotides**. Only one of the two DNA strands is transcribed. The genetic organization of the viruses is usually presented as a single strand of DNA in the form of “**open reading frames**” (**ORFs**) or **genes**, containing messages for protein formation (Fig. 11-5). There are seven early (E) ORFs, ensuring the replication of the genetic machinery of the virus, and two late (L) ORFs inscribing capsular proteins. The protein products of ORF 1 and 2 reproduce the viral genome; ORF 2 regulates the transcription of the viral genome, whereas ORFs E6 and E7 play a role in cell transformation (see below).

Classification

There are more than 70 types of HPV with several more types still not identified (Table 11-1).

The types differ from each other by 50% or more in nucleotide homology and are sequentially numbered by an international agreement, starting with type 1. Several types of HPV, that can be designated as **mucosal (anogenital) HPVs**, are observed in neoplastic lesions of the uterine cervix and other organs of the lower female genital tract. The introduction of the **polymerase chain reaction (PCR)** contributed significantly

P.289

to the identification of new HPV types and their presence in various lesions. By the use of this technique, minute amounts of viral DNA extracted from lesions could be amplified and analyzed in vitro by Southern blotting (Shibata et al, 1988; Nuovo, 1990; Nuovo et al, 1990, 1991; Bauer et al, 1991). For description of the principles of these techniques, see Chapter 3. Credits for the identification of various types of HPV are given in papers by Lorincz et al (1992) and de Villiers (2001). A novel classification system of papillomaviruses based on taxonomy was published recently by de Villiers et al (2004).

TABLE 11-1 PRINCIPAL TYPES OF MUCOSAL (ANOGENITAL) TYPES OF HPV*

HPV Type	Origin of cloned genome
HPV-6	Condyloma acuminatum
HPV-11	Laryngeal papilloma
HPV-16†	Cervical carcinoma
HPV-18†	Cervical carcinoma
HPV-31†	CIN
HPV-33†	Cervical carcinoma
HPV-34	Bowen's disease
HPV-35†	Cervical carcinoma
HPV-39†	Penile intraepithelial neoplasia
HPV-40	Penile intraepithelial neoplasia
HPV-42	Vulvar papilloma
HPV-43	Vulvar hyperplasia
HPV-44	Vulvar condyloma

HPV-45†	CIN
HPV-51†	CIN
HPV-52†	CIN
HPV-53‡	Normal cervical mucosa
HPV-54	Condyloma acuminatum
HPV-55	Bowenoid papulosis
HPV-56†	CIN, cervical carcinoma
HPV-58†	CIN
HPV-59†	VIN
HPV-61	VaIN
HPV-62	VaIN
HPV-64	VaIN
HPV-66‡	Cervical carcinoma
HPV-67	VaIN
HPV-68†	Genital lesion
HPV-69†	CIN
HPV-70	Vulvar papilloma

*Since 1994, additional types of HPV were identified as high-risk types 26, 73, 77, 82, and several others, not yet numbered (Muñoz et al., 2003).

† High risk.

‡ Probable high risk.

CIN: cervical intraepithelial neoplasia; VIN: vulvar intraepithelial neoplasia; VaIN: vaginal intraepithelial neoplasia.

Modified from IARC Monograph, Vol. 64, Human papillomaviruses. Lyon, France, 1995, with permission.

Depending on the **frequency of occurrence in invasive cancer of the uterine cervix**, the genital HPVs were initially classified as “low risk,” “intermediate risk,” and “high risk” types (Lorincz et al, 1992). The current trend is to recognize only two groups, **low-risk** and **high-risk or oncogenic viruses**. The latest classification, proposed by Muñoz et al (2003) and based on 11 case-controlled studies from 9 countries, lists 15 viral types as **high-risk** (16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 68, 73, and 82), three as **probable high-risk** types (26, 53, and 66) and 12 as **low-risk types** (6, 11, 40, 42, 43, 44, 54, 61, 70, 72, 81, and CP6108).

The most common “oncogenic” types of HPV are 16 and 18. HPV type 16 is most often observed in invasive squamous carcinomas, whereas HPV type 18 appears to have a predilection for lesions derived from the endocervical epithelium, such as small-cell carcinomas and adenocarcinomas (for discussion of these lesions, see below and Chapter

12). Type 18 and, to a lesser degree, type 16 were also identified in several cell lines derived from invasive cancers of the uterine cervix, such as HeLa, Caski, and C4-1. The distribution of HPV types in the genital tract of normal women, women with cytologic atypias, precursor lesions, and invasive cancer of the uterine cervix is shown in Table 11-2, based on a very large study by Lorincz et al (1992).

The frequency of occurrence of other oncogenic types in invasive cancer is provided by Muñoz et al (2003). A few additional points must be stressed: in a small subgroup of cervix cancer, multiple viral types were identified. In a very small number of women, **cancers were associated with the “low-risk” types 6 and 11**. In all, 90.7% of 1,918 women with cervical cancer were shown to harbor HPV DNA.

In a control cohort of 1,928 women without cervical cancer 13.4% harbored HPV DNA, mainly of high risk type. Muñoz et al calculated the **risk ratio** of cervical cancer in women infected with any type of HPV at 158 times the rate observed in women not carriers of the virus.

Life Cycle

The life cycle of HPVs takes place **in the nuclei of squamous epithelial cells** and depends on the mechanisms of epithelial maturation about which little is known. The viruses achieve their **full maturity only in the nuclei of cells forming the superficial layers of the squamous epithelium** and this phenomenon is known as a **permissive infection**. The **koilocytes are an expression of permissive infection with HPV because their nuclei are filled with mature viral particles or virions**. Electron microscopic studies of the infected nuclei have shown that the mature virions measure about **50 nm in diameter**, have an **icosahedral**, that is having 20 faces, **protein capsule**, and usually form crystalline arrays (Fig. 11-6).

In lower layers of the squamous epithelium and in other types of epithelia, the viruses do not achieve full maturity and their presence can only be detected by their DNA (occult or latent infection).

An important difference of presentation of HPV was observed between most precancerous lesions and invasive cancer (and the cell lines derived therefrom). **In precancerous lesions, the virus is usually episomal, that is, not**

P.290

integrated into cellular DNA but behaving as an independent plasmid, capable of its own life cycle, without the participation of host cell DNA. **In invasive cancer, cell lines derived therefrom, and in some precancerous lesions of high-grade, truncated sequences of viral DNA are integrated into cellular DNA** (Fig. 11-7) and their life cycle depends on the life cycle of the host cells.

TABLE 11-2 DISTRIBUTION OF VARIOUS TYPES OF HUMAN PAPILLOMAVIRUS IN CERVICAL SPECIMENS IN A COHORT OF 2,627 WOMEN FROM SEVERAL STUDIES*

Distribution of Viral Types						
HPV types*	Normal cervix†	Atypia of unknown significance	LGSIL	HGSIL	Invasive cancer	Total
None	1,465	206	115	33	16	1,835
Low risk (6/11,42-44)	14	13	76	11	0	114
Intermed. risk (31,33,35,51,52,58)	23	9	45	49	12	138
High risk (16,18,45,56)	31	22	106	153	117	429
Unknown type‡	33	20	35	15	8	111
TOTAL	1,566	270	377	261	153	2,627

Percentage Distribution of Intermediate and High Risk HPV

Normal cervix [†] N = 1,566	Atypia of unknown significance N = 270	LGSIL N = 377	HGSIL N = 261	Invasive cancer N = 153
3.4%	11.5%	40.0%	77.3%	84.3%

* HPV by Southern blot.

[†] Most had negative cytology and colposcopy.

[‡] Since this study was published in 1992, several of the "unknown" types of HPV have been identified as intermediate or high risk types 26, 39, 59, 68, 69, 73, 77, and 82.

LGSIL = low grade squamous intraepithelial lesions; HGSIL = high grade squamous intraepithelial lesions. (Modified from Lorincz et al. Obstet Gynecol 79:328-337, 1992, with permission.)

Role of Open Reading Frames E6 and E7 in Carcinogenesis

In the search for a possible carcinogenic function of HPV, it has been documented that the **proteins of the open reading frames E6 and E7 from the high-risk HPV types 16 and 18 react with proteins regulating the events in cell cycle**. Thus, the **E6 protein reacts with p53**, which is one of the key regulatory genes governing the transcription of DNA in the G1 phase of the cell cycle and leads to its degradation (Chen et al, 1993). **E7 protein reacts with the Rb gene**, which governs the orderly transition of cells from G₁ to G₂ phase of the cell cycle and leads to its degradation (Fig. 11-8). The reactions require intermediate molecules, including **ubiquitins**. **Loss of the open reading frame E2** that has a regulatory function is probably important in this sequence of events (Dowhanick et al, 1995). It has been fairly universally assumed that this relationship of the E6 and E7 proteins contributes to events leading to carcinoma of the uterine cervix (summaries in Shah and Howley, 1992; Howley, 1995; Munger et al, 1992). In experimental systems, the activation of E6 and E7 genes proved to be important in immortalization of normal human squamous cells in culture by HPV types 16 or 18 (De Palo et al, 1989; Woodworth et al, 1989; Montgomery et al, 1995). The E6 and E7 genes are usually well preserved and, perhaps, even enhanced in the integrated viral DNA, possibly contributing to the malignant transformation (Einstein et al, 2002).

In this context, it is important to note that **other DNA viruses, such as adenovirus and simian virus 40 (SV 40), interact with p53 and Rb genes more efficiently than HPV but are not carcinogenic in humans. Thus, additional mechanisms must be operational to explain the carcinogenic role of HPV** (Lazo, 1999).

HPV in Precursor Lesions and Cancer of the Uterine Cervix

The earliest study documenting the presence of HPVs in a neoplastic lesion of the cervix were based on **electron microscopy** of biopsies of the cervix, cited above, and extended to corresponding cells in smears by Meisels et al (1983). By this technique, only the mature virions of unknown type can be demonstrated in the nuclei of the affected cells (see Fig. 11-6). Another technique suitable for demonstration of mature virions was based on an **antibody to common antigen** contained in capsids of bovine papillomavirus (Jenson et al, 1980). Using an immunologic technique on tissue sections of precursor lesions, it was shown that the presence of **mature virions was generally limited to the nuclei of cells in the upper layers of the squamous epithelium, notably the nuclei of koilocytes** (Fig. 11-9A). A positive reaction with the nuclei of cells of the basal layer was exceptional. This technique was applied to abnormal cells in smears by Jean Gupta et al (1983), but provided no information on latent infection.

P.291

Figure 11-6 Light and electron microscopic presentation of koilocytes. The light microscopic appearance of these cells is shown in *D*. Note the enlarged single or double nuclei and the sharply demarcated perinuclear clear zone surrounded by a narrow rim of cytoplasm. *A,B*. Electron micrographs of koilocytes from a cervical smear. In *A*, an array of viral particles is present in the nucleus and there is a near-complete destruction of the perinuclear cytoplasm, accounting for the perinuclear “cavity” in light microscopy. In *B*, the crystalline array of viral particles, each measuring approximately 50 nm in diameter. *C*. Immunoperoxidase-labeled HPV antibody reaction (black stain) in nuclei of a histologic section of a vulvar condyloma, treated with a broad spectrum antibody to papillomaviruses. (*A*: $\times 5,590$; *B*: $\times 44,200$.)

To identify latent infection and to determine the relationship of specific viral types to human disease, molecular hybridization techniques were required. The general principle is based on **hybridization homology between a known DNA sequence and the unknown target DNA** (see Chap. 3 for a description of the basic principles of these techniques). An essential first step was the unraveling of the molecular structure of the viruses of various types, leading to the production of **type-specific DNA probes** (zur Hausen, 1976; Gissmann et al, 1983). The hybridization techniques can be used under **stringent** or **nonstringent** conditions. The nonstringent conditions may reveal the presence of viral DNA of several related viral types. Under stringent conditions, only one specific viral type will be demonstrated.

P.292

Figure 11-7 Schematic representation of nonintegrated and integrated human papillomavirus DNA (red dots).

Figure 11-8 Diagram of the impact of HPV proteins E6 and E7 on various stages of cell cycle. The protein E6 interacts with p53 affecting the G1 stage of the cell cycle. Protein E7 reacts with retinoblastoma (Rb) gene and, thus, with the terminal phase of G1 and the beginning of S phase of the cell cycle. Ubiquitin mediates degradation of both tumor suppressor proteins, thus facilitating the expression of genes needed for completion of cell cycle. (Courtesy of PALazo. The molecular genetics of cervical carcinoma. Br J Cancer 80:2008-2018, 1999.)

P.293

Figure 11-9 A. Anal condyloma stained with immunoperoxidase-labeled antibody to broad spectrum capsular antigen of HPV. The dark nuclei contain viral particles. **B.** In situ hybridization of a low-grade squamous intraepithelial lesion of cervix with a probe to HPV type 16. The dark brown-stained nuclei contain viral DNA.

Southern blotting technique remains the “gold standard” of such studies because of its sensitivity and specificity. The technique can be applied to liquid samples collected from the cervix or vagina of patients or to DNA extracted from specific lesions. It was **assumed that the viral type in the liquid sample corresponded to the viral type present in the lesion**. By this technique, initial information could be obtained on the presence of various types of HPV in DNA extracted from various lesions, such as invasive cancer. The technique also provided information on the relationship of the viral DNA to the genomic DNA, that is, whether the viral DNA was episomal or integrated, but provided no information on the distribution of viral DNA in lesions.

In situ hybridization of tissue sections with probes to various types of HPV provides information on the distribution of specific types of viral DNA in histologically identified specific lesions (Fig. 11-9B). The probes can be labeled with either radioactive compounds, requiring lengthy exposure and development of photographic plates, or with biotin for a rapid microscopic visualization of the positive immune reaction. An imaginative application of the in situ hybridization technique is the use of **antisense RNA probes**, which hybridize to mRNA produced by the virus and, hence, reveal active viral transcription (Stoler and Broker, 1986). A relatively simple **dot blot hybridization** technique can be used for screening of cell samples suspended in a liquid medium. The latter technique allows synchronous analysis of multiple samples. Cell DNA is placed (spotted) onto a nitrocellulose membrane, denatured by heat, and hybridized with viral DNA labeled with a radioactive probe under stringent conditions.

The identification of viral presence is facilitated by **polymerase chain reaction (PCR)**, to amplify small amounts of DNA extracted from cells or tissues. Probes to most viral types are now commercially available and the procedure has been automated. Most recent studies describing the relationship of HPV with cervical cancer are based on this technique. **PCR** may also be used **in situ** in cells and tissues with markedly increased sensitivity (Nuovo et al, 1991; Bernard et al, 1994) but the technique is difficult and prone to errors. Most recently, a **hybrid capture technique** has been developed to document the presence of the virus in liquid samples obtained from the female genital tract (Lörincz, 1996). The principles of the technique are described in the legend to Figure 11-10. The test has been automated with apparently reliable results. It was approved by the Food and Drug Administration (FDA) in 2003 as an ancillary test for evaluation of precancerous lesions of the uterine cervix (see Part 2 of this chapter for further discussion of this topic).

The **sensitivity of these techniques varies significantly**. Common capsid antigen has low sensitivity and requires a fairly massive presence of mature virions to be positive. Southern blotting may give a positive signal with a small number of viral copies. Dot blotting, used as a screening test, has moderate sensitivity. The in situ hybridization techniques with DNA probes are less sensitive than Southern blotting and require from 10 to 50 copies of viral DNA for the signal to reveal the presence of the virus. In situ hybridization with RNA probes is more sensitive. With the use of the PCR, a single copy of the virus can be detected. Hybrid capture technique appears to have a sensitivity similar to Southern blotting.

Evidence Supporting the Role of HPV as a Carcinogenic Agent

Over the past decade, the literature on this topic has grown exponentially and only a very brief summary of the salient facts can be given here. **The presence of high-risk (including intermediate-risk) HPVs has been documented in nearly all invasive cancers and in 50% to 90% of precancerous lesions** (Lorincz et al, 1992; zur Hausen, 1994; Bosch et al, 1995; Fahey et al, 1995; Howley, 1995; Shah and Howley, 1995; Kleter et al, 1998; Lazo, 1999; Burk, 1999; Muñoz et al, 2003). The highest figures, published since 1990, were based on PCR, which allowed for the

P.294

detection of minute amounts of viral DNA in target tissues or cells. It is generally thought that integration of HPV into the cell genome and the affinity of the oncoproteins E6 and E7 for the p53 and Rb regulatory proteins are the triggers leading to the multiple genetic abnormalities that are the hallmark of cancer. In 1995 a **committee of experts** convened by the IARC, **declared HPV 16 to be a carcinogenic agent** and HPV types 18 and 31 as probable carcinogenic agents (see IARC Monograph 1995 for a detailed analysis of the published data). Latest classification by IARC team was discussed above (Muñoz et al, 2003).

Figure 11-10 The Hybrid Capture II HPV test is a second-generation DNA test that relies on signal amplification to achieve high sensitivity. Specimens are treated with a denaturant to break up cell DNA to form single-stranded DNA. Then HPV-specific RNA probes are added and hybridization is allowed to proceed. If there is a specific HPV type in the specimen, its genomic DNA will form an RNA-DNA hybrid. These hybrids are captured on a microplate well and reacted with an alkaline phosphatase monoclonal antibody conjugate specific for RNA-DNA hybrids. Unbound molecules are removed by washing, and the hybrid conjugates are detected by chemiluminescence produced by the dephosphorylation of a dioxetane-based substrate. The test has been approved by the FDA as an ancillary

method of screening for carcinoma of the uterine cervix. (Courtesy of Dr. Attila Lőrincz, Digene Corp., Gaithersburg, MD 20878; modified.)

Initial studies of patients suggested that the mere presence of HPV was a risk factor for the development of cancer of the cervix. Subsequent studies in women with normal cervicovaginal smears gave inconsistent results, ranging from 0 in virgins (Fairley et al, 1992) to 47% (ter Meulen et al, 1992) in various populations from several continents (for summary, see IARC Monograph 1995 and Muñoz et al, 2003). **Follow-up of patients, with or without cytologic abnormalities, suggested that women carriers of HPVs, particularly of the high-risk type, are at risk for developing intraepithelial precursor lesions, some of which are high-grade** (de Villiers et al, 1992; Koutsky et al, 1992; Schlecht et al, 2001). Burk (1999) estimated that women carriers of the virus were three times as likely to develop precancerous lesions as women free of virus.

With the introduction of the sensitive PCR method of virus detection, in a number of studies of various populations of healthy young women in the United States, it has been shown that **the presence of HPV, mainly of high-risk type, could be documented in nearly half of them** (Bauer et al, 1991). The proportion of women carriers of high-risk HPV increased with the number of sexual partners, reaching 100% in those with 10 sexual partners (Lay et al, 1991). **Clearly, only a tiny fraction of these women would be likely to develop cancer of the cervix. Serologic methods** of immunotesting for the past or current infection with HPV have also been conducted, searching for antibodies

P.295

to viral capsids (Kimbauer et al, 1994; Viscidi et al, 1997; Rudolf et al, 1999). The method appears to be efficient in identifying people exposed to the virus (usually type 16), but its clinical value has not been proven.

It was subsequently documented that, **in most young women, the presence of the virus is transient and of no apparent clinical significance**. Ho et al (1998) documented that **the dominant type of virus may change with each test**. Moscicki et al (1998) followed 618 women positive for HPV; in 70% of them, the presence of the virus could no longer be documented after 24 months. In women with persisting infection, only 12% developed precursor lesions. **Normal pregnant women** are frequent carriers of HPV. Depending on the trimester of pregnancy, 30% to 50% of women showed evidence of HPV infection, half of them of the high-risk type (Schneider et al, 1987). Rando et al (1989) reported that the proportion of women with HPV DNA rose from about 21% in the first trimester of pregnancy to 46% in the third trimester. Thus, **the presence of the virus in pregnant women is transient and is related to somewhat lowered immunity occurring during pregnancy**.

Because the proportion of normal women carriers of the virus is extremely high, **a new theory had to be constructed, to wit, that only persisting infections with viruses of high-risk type lead to precancerous lesions and, by implication, to invasive cancer**. Several follow-up studies, notably by Ho et al (1995); Walboomers et al (1995); Moscicki et al (1998); Chua and Hjerpe (1996); and Wallin et al (1999), presented persuasive evidence that women with persisting infection with a high-risk type HPV were at risk for the development of high-grade lesions and, by implication, invasive cancer of the cervix. Perhaps the most interesting prospective studies were conducted in the Netherlands (Remmink et al, 1995; Nobbenhuis et al, 1999). In the Remmink study 342 women with cytologic diagnosis of "Pap IIb," a suspicious smear suggestive of some form of intraepithelial neoplasia, were followed for about 16 months. Every 3 to 4 months, the women were examined by colposcopy (without biopsies) and HPV DNA testing for 27 "high risk" types was performed by using the PCR method. At the start of the follow-up, 62% of the women were HPV-positive. At the conclusion of the study 19 women (5.6% of the cohort) who were HPV positive throughout the study, progressed to CIN III, occupying two or more quadrants of the cervix. In the Nobbenhuis study, 353 women with a cytologic diagnosis of mild, moderate, or severe dyskaryosis and, hence, some form of "dysplasia," were followed, as in the Remmink study, for a period of over 5 years. Thirty three (9.3%) of the cohort developed a high-grade precursor lesion (CIN III) occupying three or more quadrants of the uterine cervix, all having been HPV positive throughout the study period. The conclusions of the Dutch studies stated that women with **persisting infection with a high-risk HPV** were those most likely to develop an extensive high-grade neoplastic lesion. At the time of this writing (2004), it is the consensus of the investigators that persisting infection with a high-risk HPV causes cervical cancer (Manos et al, 1999; Stoler, 2000; Schlecht et al, 2001). **Still, cancer of the uterine cervix is, at best, a rare complication of HPV infection, as recently confirmed by the Dutch investigators who were among the most active promoters of the HPV-cancer relationship** (Helmerhorst and Meijer 2002).

An important, although indirect, confirmation of the role of HPV 16 in carcinogenesis of the uterine cervix has been the development of a **vaccine**, first in mice (Balmelli et al, 1998) and

then in humans. In preliminary trials, the vaccine has been shown to be protective of HPV-associated precancerous abnormalities (Koutsky et al, 2002).

Unresolved Questions

- **It is evident that the presence of HPV, even in the high-risk type, in the genital organs of a woman, does not constitute evidence of a precancerous event or cancer.** Studies of persisting infection with high-risk HPV, summarized above, do not address the question why some women have a persisting HPV infection and most do not, why only a small percentage of the women with persisting infection will develop precancerous lesions, nor does it address the question of what percentage of women with CIN III will progress to invasive cancer. In my view (LGK), this algorithm represents a simplistic explanation of a very complex problem and raises many questions that have not been addressed to date.
- **The frequency of documented viral presence diminishes with age.** It is highest in teenagers and in women in the third decade of life, but becomes much lower in the fourth and subsequent decades. **Yet, invasive cancer of the uterine cervix has its peaks in the fourth and fifth decades of life,** hence, the conclusion that **the virus must remain latent for many years and yet remain active to induce the multiple molecular genetic changes that are a prerequisite of invasive disease.** Virtually nothing is known about these events.
- **There are no specific associations of HPV types with precursor lesions of cervix cancer.** All HPV types, whether low-, intermediate-, or high-risk, occur in precursor lesions, regardless of their morphologic configuration and classification as either low-grade or high-grade (see Table 11-2). Thus, **the severity of the abnormality in a precursor lesion cannot be correlated with viral type.** The end point, usually invasive cancer of the cervix, but not always, correlates with high-risk viral types but it represents only a very small fraction of infected women.
- **The behavior of intraepithelial precursor lesions, whether high- or low-grade, is insecure.** Although many of them, particularly the low-grade lesions, may regress or persist without progression, some other lesions of identical morphologic configuration may progress to invasive cancer, as is discussed later on in this chapter. **In the absence of long-term prospective follow-up studies of the precursor lesions, their insecure behavior has not been correlated with viral types.** In attempting to explain the mechanisms controlling the behavior of these lesions, Kadish et al (1997) have suggested that the immune response in the patients' cervical

P.296

stroma may be the decisive factor accounting for this behavior. Kobayashi et al (2002) observed the presence of lymphoid aggregates in the stroma of the cervix in the presence or absence of neoplastic lesions but failed to correlate the findings with behavior. In keeping with the viral persistence theory, discussed above, it has been suggested that women who get rid of their virus may have regressing lesions, but such a study has not been conducted to date.

- **The mechanisms of viral transmission.** It is generally assumed that HPV is transmitted between sexual partners. In support of this thesis, it has been shown that **the presence of HPV in sexually active young women increases with the number of sexual partners, reaching 100% in women with 10 partners** (Ley et al, 1991). However, tracing the virus to male partners has proven to be difficult. Initial studies of penile lesions in male partners of women with precancerous lesions of the uterine cervix suggested that in 50% to 70% of the males, inconspicuous lesions on the skin on the shaft of the penis, detected with a colposcope, may be the source of the infection (Barrasso et al, 1987). In a subsequent communication in a French journal (1993), Barrasso et al reduced this figure to 35% to 40% of males. In a study by Baken et al (1995) using PCR, the **presence of any type of HPV in both sexual partners occurred in only about half of the couples and matching viral types were relatively uncommon;** a complex analysis was used to show that the limited concordance was statistically significant. Castellsqué et al (2002) reported that circumcision in males has a protective effect on males and their female partners. It is beyond the scope of the present work to cite additional references on this topic and the reader is referred to the IARC Monograph (1995) for additional reading. At the time of this writing, **the source of the viral infection is not clear in many female patients with neoplastic lesions of the uterine cervix.**
- Further, the presence of HPV sequences in carcinomas of the **cornea, larynx, esophagus, and lung,** discussed below, strongly suggest that **sexual mode of transmission is not the only mechanism of activation of HPV** which has great affinity for squamous cancer of many organs.

- **Mechanism of infection.** It is currently assumed that the infection of the epithelium with HPV occurs at the level of the basal layer of the squamous epithelium of the cervix, this being the only part of the epithelium capable of mitotic activity necessary to induce epithelial transformation. There are many aspects of this assumption that have not been proven. For example, it is not known whether mature virions or sequences of viral DNA are capable of infecting the target epithelium. It is not known whether receptors exist on the surfaces of the target cells to capture the virus and to facilitate the transfer of viruses into the cell interior. It is not known how the viruses travel across the cytoplasm to reach the nucleus.
- Therefore, the **carcinogenic role of the virus can only take place under certain conditions that favor its persistence.** Little is known about these **risk factors** but one of them may be the **immunodeficiency.** The first study to this effect was a report from this laboratory on four immunodeficient female patients (three of them with **Hodgkin's disease**) who developed multifocal HPV-related precancerous lesions in their genital tracts, which in one of them progressed to invasive cancer. The presence of the virus in the precancerous lesions was documented by electron microscopy in all four patients (Shokri-Tabibzadeh et al, 1984). A similar observation was made by Katz et al (1987) in a larger group of patients with Hodgkin's disease. **Immunosuppressed organ-transplant recipients** also show a high rate of cutaneous warts and cervical carcinoma in situ (Baltzer et al, 1993; also see Chapter 18). A high frequency of viral infection and precancerous lesions is observed in immunosuppressed women, particularly women infected with human immunodeficiency virus (HIV) and women with **AIDS** (Schrager et al, 1989; Feingold et al, 1990; Maiman et al, 1990, 1993; Klein et al, 1994; Sun et al, 1997; Palefsky et al, 1999; Ellenbrock et al, 2000). We have observed evidence of HPV infection in **female children** treated with chemotherapy (see Fig. 18-7A) and in **women past the age of 80 or even 90.**
- It has been proposed (Koss, 1989, 1998) that **a nonsexual mode of viral infection may exist** and that the infection may occur at birth and remain latent and not detectable until the virus is activated under circumstances related to the onset of sexual activity. The **presence of HPV in neoplastic lesions of many organs other than the genital tract is in favor of this concept.** Galloway and Jenison (1990) and Jenison et al (1990) observed high rates of serologic positivity, as evidence of past infection, in normal adults and in children, using antibodies to fusion proteins of HPV. In subsequent studies, using antibodies to capsids of HPV type 16, seropositivity was limited to some patients with documented past or current infection (Carter et al, 1996). The possibility of **viral transmission at birth** was investigated by Sedlacek et al (1989) by studying nasopharyngeal material in newborn infants. In 15 of 45 infants, the presence of viral DNA could be documented by Southern blotting. Also 2 of 13 amniotic fluid samples contained HPV DNA. **Perinatal transmission of the virus** was also studied by Tseng et al (1998) and by Tenti et al (1999). In both studies, from 22% to 30% of the infants were shown to carry the virus, although the long-term significance of this observation is still under debate. However, a prospective study by Watts et al (1998) considered the risk of perinatal transmission of the virus as very low.
- **Assuming that a nonsexual mode of viral transmission does exist,** the activation at the onset of sexual activity would have to be explained. The possible role of **spermatozoa** as a carcinogenic agent has been discussed above and is deserving of further investigation. Another possible risk factor that has not been investigated so far is the possibility that the amount of exposure may be important; a "**superinfection**" with a massive number

P.297

of virions may be significant, especially in very young teenagers who were shown to be particularly susceptible to this infection (Hein et al, 1977). Zur Hausen (1982) also speculated on the possible role of **synchronous infection with herpesvirus type 2.** Ho et al (1998) speculated that cigarette smoking may be a risk factor (see above).

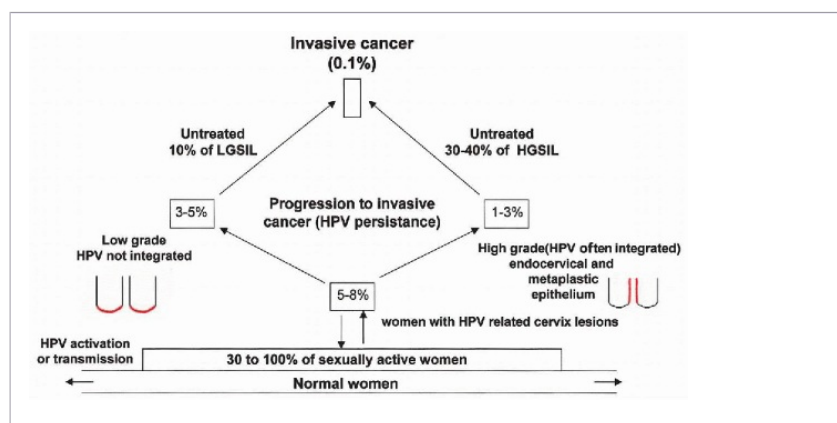

Figure 11-11 Diagram summarizing the probable sequence of events leading from the very common human papillomavirus infection to the rare invasive cancer of the uterine cervix. Two patterns of disease are recognized. The untreated low-grade squamous intraepithelial lesions (LGSIL, *left*) infrequently progress to invasive cancer. The progression of untreated high-grade intraepithelial lesions (HGSIL, *right*) is more common but still far from certain. The figures are approximate and reflect the writer's preferences and concepts.

There is no doubt that HPV is associated with precancerous and cancerous lesions of the female genital tract and that behavioral factors play a role in the development of these lesions. To paraphrase Pagano's comment on the role of Epstein-Barr virus in nasopharyngeal carcinoma (1992): *Is the HPV a "passenger," a "driver," or both?* (cited by Koss 1998). Several issues of importance have been discussed above. A possible sequence of events in the relationship of HPV to precancerous and cancerous lesions of the uterine cervix is shown in Figure 11-11.

HPV Testing for Triage and Diagnosis of Precancerous Lesions of the Uterine Cervix

Within the recent years, numerous papers have been published describing the results of HPV testing as a means of detection and characterization of precancerous lesions of the uterine cervix. The initial observations pertaining to the prognostic significance of persistence of the virus have been cited above. The use of HPV testing, usually by the Hybrid Capture technique, discussed above, was investigated among others by Vassilakos et al (1998), Sherman et al (1998), Manos et al (1999), Cox et al (1999), Denny et al (2000), Schiffman et al (2000), Wright et al (2000), and Zuna et al (2001).

All observers agree that the testing is possible and reliable when performed on residual cells from liquid cytologic samples but **vary widely in assessment of the utility of the test** as a method of cancer detection. The most important argument against this application of HPV testing is the very large number of false positive tests in sexually active young women (Clavel et al, 1999; Bishop et al, 2000; Davey and Armenti, 2000; Koss, 2000; Cuzick, 2000).

Although the performance of the cervicovaginal cytology is labor intensive and, therefore, costly, whereas HPV testing could be automated, the utility of the test as a cancer detection tool replacing the Pap smear is a saving of doubtful value.

The application of HPV testing in the assessment of atypical squamous or glandular cells of unknown significance (ASC-US, AGUS) is discussed in Part 2 of this chapter.

HPV in Organs Other Than the Uterine Cervix

Most HPV types are observed in **skin lesions**; several were identified in a rare hereditary skin disorder, sometimes leading to skin cancer, known as **epidermodysplasia verruci-formis**

P.298

(Orth, 1986). **Bowenoid papulosis**, usually a **self-limiting disease of the anogenital skin** occurring as brown papules, mainly in young sexually active people, was shown to be associated with HPV type 16; this disorder is now considered a source of viral transmission between sexual partners.

Anal lesions, which are similar to the lesions of the uterine cervix, will be discussed in Chapter 14. The occurrence of condylomas on the **penis** is well known. A lesion of the shaft of the penis, which is intermediary between a condyloma and a low-grade squamous cancer, known as the **giant condyloma of Buschke-Loewenstein**, usually contains HPV 6. Invasive squamous cancer of the penis, rare in the developed countries, but fairly common in Latin America and in Africa, often contains HPV 16. However, **the presence of high-grade precancerous lesions, either on the shaft of the penis or in the penile urethra, has not been well documented**, an issue of importance in epidemiology of HPV (see above).

Squamous carcinomas in situ (Bowen's disease) and invasive squamous cancers of the vulva were shown to contain several viral types, including 6, 11, and 16. The references pertaining to these lesions will be found in the appropriate chapters and in the IARC Monograph (1995).

Several studies linked **oral cancer** with various types of HPV, particularly types 6 and 16 (Maden et al, 1992). For further discussion, see Chapter 21. **Laryngeal papillomatosis**, an uncommon chronic disorder of the larynx, observed mainly in children (juvenile form) but occasionally in adults, has been shown to be associated with **HPV types 6 and 11** (Mounts et al, 1982; Steinberg et al, 1983; Lele et al, 2002). It is likely that the juvenile form of laryngeal papillomatosis may be the result of contamination of the infant with the virus at birth, during passage through the vaginal canal. Byrne et al (1986) have shown that the **laryngeal lesions may become malignant** and form **metastases containing HPV type 11**, an observation

confirmed on four additional patients by Lele et al (2002). Condylomas of the **urinary bladder** were shown to contain HPV types 6 and 11 (Del Mistro et al, 1988; see Chapter 22). Precancerous lesions and cancer of the **conjunctiva and the cornea of the eye** (McDonnell et al, 1989) **and carcinomas of the esophagus in China** (Chen et al, 1994) have been shown to contain HPV type 16 (see Chapter 24). Another candidate for the observation with HPV is squamous cancer of the lung (Syrjänen et al, 1989; Papadopoulou et al, 1998), although this association requires further confirmation. It is evident that, in most of these situations, sexual transmission of the virus is extremely unlikely.

SEQUENCE OF MORPHOLOGIC EVENTS IN THE DEVELOPMENT OF CERVIX CANCER

Over the years, many attempts have been made to establish a logical sequence of morphologic events in the genesis of invasive cancer of the uterine cervix. A progression of intraepithelial lesions from slight to marked to invasive cancer has been postulated (Cain and Howell 2000). Unfortunately, the reality defies such simplistic schemes. As is set forth below, **although a transformation of the initial low-grade lesions to high-grade lesions may occur, it is a relatively uncommon event. Most high-grade lesions develop independently in adjacent segments of endocervical epithelium.** The sequence of events is illustrated in Figure 11-12. The behavior of precancerous lesions is discussed below.

Initial Events: Low-Grade Squamous Intraepithelial Lesions (LGSIL)

The initial events in carcinogenesis of the uterine cervix occur in **most, but not all, cases** within the **squamous epithelium** in the area of the **squamocolumnar junction** or **transformation zone** (Fig. 11-12A). Ferenczy and Richart (1974) have shown, by scanning electron microscopy, that the surface configuration of the squamous epithelium of the transformation zone is characterized by smaller cells lacking the microridges characteristic of mature squamous epithelium (Fig. 11-13). It is not known whether this feature is of significance in carcinogenesis.

The earliest morphologically identifiable precancerous tissue lesions (**LGSIL, or mild dysplasia**) are characterized by **enlarged and hyperchromatic nuclei, and the presence of normal and abnormal mitoses, occurring at various levels of the reasonably orderly squamous epithelium** (Figs. 11-12B, 11-14). In **some of these lesions, the abnormal nuclei are surrounded by a clear cytoplasmic zone (koilocytes)** that provide morphologic evidence of a **permissive human papillomavirus infection with a variety of viral types** (see Fig. 11-9B). In **some cases, the squamous epithelium is thickened, folded, and provided with a superficial layer of keratinized cells.** Such lesions resemble a wart or a *condyloma acuminatum* and, therefore, are sometimes referred to as a “**flat condyloma**,” a term that is no longer recommended (see Fig. 11-4 and Part 2 of this chapter).

The early neoplastic events may also take place outside of the transformation zone, either on the native squamous epithelium of the uterine portio or in the endocervical epithelium. The lesions on the native squamous epithelium are identical to those occurring in the transformation zone, described above. The early neoplastic events occurring in endocervical epithelium are difficult to recognize or classify and are generally known as **atypical squamous metaplasia**, discussed in Chapter 10 and again further on in this chapter.

Studies of populations of women with multiple cytologic screenings show that, after elimination of all precursor lesions, the predominant **new lesions** observed in such women are the low-grade squamous lesions described above (Melamed et al, 1969) (Fig. 11-15). **The incidence of these lesions is approximately 5 to 6 per 1,000 women's years. The prevalence depends on the type of population studied and ranges from 1 to 5%, occasionally somewhat higher.** Although most initial lesions are generally **first observed in young women or even adolescents** (Hein et al, 1977), **they may also be observed in older women, even after the menopause.**

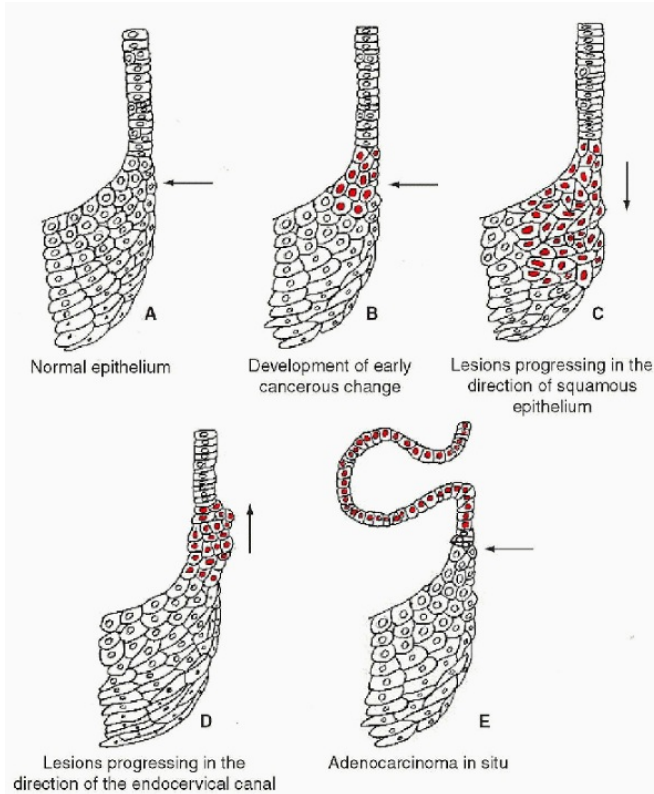

Figure 11-12 Sequence of events in the development of precancerous lesions of the uterine cervix. A. Normal cervix. Horizontal arrow indicates transformation zone (TZ). B. Early neoplastic events (red dots) occurring in the TZ (horizontal arrow). C. Lesion progressing from the transformation zone to squamous epithelium of the outer cervix, resulting in low-grade squamous intraepithelial lesion (LGSIL; arrow down). These lesions may sometimes progress to squamous carcinoma. D. Lesion progressing from the TZ in the direction of endocervical canal (arrow up), resulting in high-grade intraepithelial lesions (HGSIL). E. Development of endocervical adenocarcinoma (TZ; horizontal arrow). Events depicted in C-E may be synchronous. (Drawing by Prof. Claude Gompel, Brussels, Belgium.)

Figure 11-13 Scanning electron micrograph of the transformation zone. The mature squamous epithelium forms a ridge around the central zone (transformation zone), wherein the component squamous cells are much smaller. The external os is seen as a comma-shaped opening. (×220.) (Courtesy of Drs. A. Ferenczy and R.M. Richart, New York, NY.)

Figure 11-14 Low-grade squamous intraepithelial lesions (LGSILs) of the uterine cervix. *A.* The similarity of the lesion with condylomas shown in Figure 11-4B is striking. Also note the superficial layers of keratinized cells. *B.* The squamous epithelium is of normal thickness but shows nuclear abnormalities and koilocytes in the upper epithelial layers.

High-Grade Squamous Intraepithelial Lesions (HGSIL)

There is excellent evidence that most cases of HGSIL develop in the endocervical epithelium, either within the transformation zone or in the endocervical canal, as confirmed by mapping studies (see Fig. 11-12C,D). The HGSIL may be adjacent to LGSIL (Fig. 11-16A) or occur in the absence of LGSIL, as a primary event (Fig. 11-16B).

There are three principal histologic patterns of HGSIL.

Figure 11-15 Results of several sequential annual cytologic screenings with histologic confirmation. The lesions are divided into three groups; borderline (consistent with mild to moderate [low-grade] dysplasia, or CIN I), suspicious (consistent with high-grade dysplasia, or CIN II), and carcinoma in situ (corresponding to CIN III). It may be noted that with the elimination of the more severe lesions the prevalence of the borderline lesions remains essentially unchanged year after year. (From Koss LG. Significance of dysplasia. Obstet Gynecol 13:873-888, 1970.)

About 60 to 70% of these lesions mimic squamous metaplasia and are characterized by medium size cancer cells, about the size of metaplastic cells, showing enlarged, hyperchromatic nuclei throughout the epithelium of variable thickness that shows moderate to marked disturbance of layering (Fig. 11-16C).

In about 15 to 20% of cases, the neoplastic process is derived **from the basal or reserve cells of the endocervical epithelium** and results in **lesions composed of crowded small cancer cells with scanty cytoplasm** (Fig. 11-16B,D). **Adenocarcinomas of the endocervix probably share the same origins with high-grade lesions of this type** (see Fig. 11-12E and Chapter 12).

High-grade squamous lesions of metaplastic and small cell type **frequently extend to endocervical glands** (Fig. 11-16D). **This extension should not be considered as evidence of invasion.** In such lesions, **human papillomavirus infection is usually occult** and the documentation of the

P.301

presence of the viral DNA requires hybridization or other molecular techniques.

Figure 11-16 High-grade squamous intraepithelial lesions (HGSIL) of the uterine cervix. *A.* Shows the presence of a low-grade lesion on the right and of a high-grade lesion on the left. The latter extends into the adjacent endocervical gland. *B.* HGSIL composed of medium-size cells in the endocervical canal. *C.* HGSIL mimicking squamous metaplasia of the endocervix. Note nuclear abnormality, mitotic figures and disorderly arrangement of cells. *D.* Small cell HGSIL extending into endocervical glands.

The third, currently least frequent histologic pattern of HGSIL, is the **high-grade lesion of squamous type**, known as either **keratinizing carcinoma in situ or keratinizing dysplasia that usually retains many morphologic features of the squamous epithelium of origin** (Fig. 11-17A). These lesions **develop in LGSIL** that, for reasons unknown, progress to HGSIL. **Such lesions are usually located on the outer portion of the cervix, may spread to the adjacent vagina, and may retain the features of the permissive human papillomavirus infection, such as koilocytosis.** It is uncommon for these lesions to extend to the endocervical glands.

All **high-grade lesions**, regardless of type, contain **abundant mitoses at all levels of the epithelium, some of which are abnormal, such as the so-called tripolar mitoses** (Fig. 11-17B). In some of these lesions, the malignant epithelium shows **two sharply demarcated layers** (Fig. 11-17C). Usually, the top layer is composed of larger, better differentiated cells than the bottom layer. The mechanism of this event is unknown. HGSIL may sometimes **coat the endometrial surface** (Fig. 11-17D). This is a very uncommon event, usually associated with invasive cancer elsewhere in the cervix.

In histologic material, the different patterns of precursor lesions may be present on the same cervix side-by-side. The differences in the epithelium of origin and anatomic location of the intraepithelial lesions are reflected in histology and cytology of these lesions and may have considerable bearing on the interpretation and classification of biopsies and cervicovaginal smears.

The prevalence of high-grade squamous lesions varies according to the population studied from 0.5% to 3% and, hence, is generally much lower than that of the low-grade lesions.

Also, the high-grade lesions are usually **observed in women who are somewhat older than those with low-grade lesions and younger than women with invasive carcinoma.** The peak of prevalence falls between 25 and 40 years of age (Melamed et al, 1969). The age difference between women with high-grade lesions and those with invasive cancer has been variously estimated at 6.6 to 20 years. In other words, one can expect a latency period of several years until a precursor lesion becomes invasive, thus increasing the chance of its

discovery by a systematic screening.

P.302

Figure 11-17 High-grade squamous intraepithelial lesions (HGSIL). *A.* Note the marked formation of keratin on the epithelial surface. *B.* High magnification view of HGSIL showing a tripolar mitotic figure. *C.* Two-layer arrangement of HGSIL. As is common in these lesions, the upper part is composed of larger, better differentiated cells than the lower part of the lesion. *D.* HGSIL coating the surface of endometrial cavity. Elsewhere, this tumor was invasive.

Mapping Studies of Precursor Lesions

Extensive mapping studies by Foote and Stewart (1948) (Figs. 11-18, 11-19, 11-20 and 11-21), Przybora and Plutowa (1959), Bangle (1963), Burghardt and Holzer (1972), and Burghardt (1973) confirmed that **keratinizing squamous high-grade lesions are usually located on the outer surface of the cervix** (corresponding to the location of the low-grade lesions), whereas the **high-grade lesions of the endocervical (metaplastic) type, composed of cells of medium sizes, are located in the transformation zone and the endocervical canal. However, lesions composed of small cells are usually confined to the endocervical canal.** The summary of these observations is shown in Figure 11-21.

Behavior of Precursor Lesions

Follow-up studies of precursor lesions, regardless of histologic type, **have shown that the behavior of these lesions is unpredictable. Many of these lesions, particularly of the low-grade type, may vanish without treatment or after biopsies. Other precursor lesions may persist without major changes for many years and may undergo atrophy after the menopause**, in keeping with the atrophy of normal epithelia of the female genital tract. **On the other hand, invasive cancer may follow any type of precursor lesion, although it is much more likely to develop from high-grade lesions. However, epidemiologic data strongly suggest that invasive cancer is a relatively rare event, occurring in only approximately 10% of the intraepithelial precursor lesions** (Koss et al, 1963; Östör, 1993; Herbert and Smith, 1999). An example of the behavior patterns of a precursor lesion is shown in Figure 11-22. Regardless of these considerations, because most invasive cancers are derived from high-grade lesion, it is the consensus among gynecologists that the high-grade lesions represent a clear and present danger to the patients and, therefore, should be treated. **Prognostic factors** under current investigation are discussed below.

Behavior and Staging of Invasive Carcinoma

Intraepithelial precursor lesions, regardless of degree of histologic or cytologic abnormality, do not endanger the life of the patient because they are not capable of producing metastases. **The onset of danger is related to invasion, which occurs when the cancerous process breaks out of the epithelial confines through the basement membrane into the stroma of the uterine cervix.** The biologic circumstances accounting for invasion are not clear and the many hypotheses are discussed in Chapter 7.

P.303

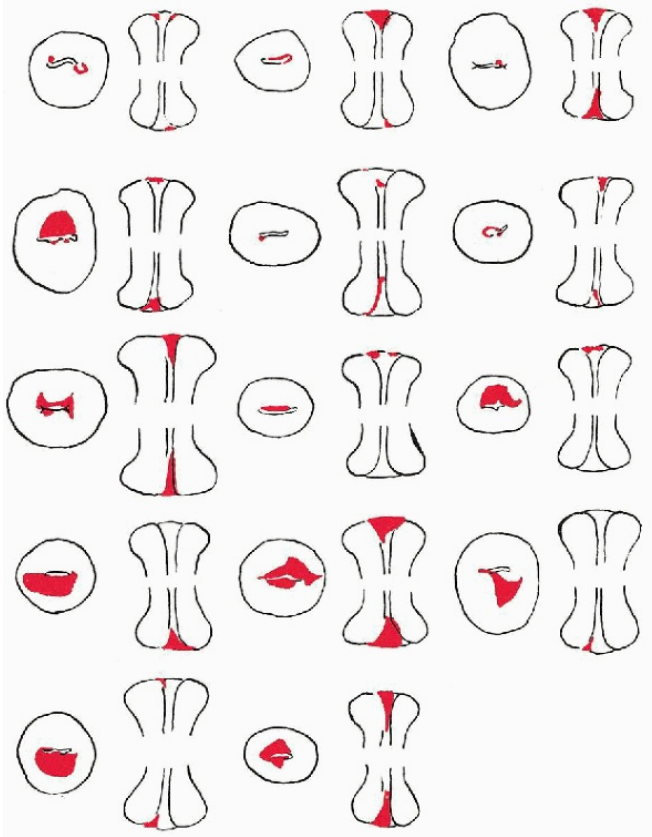

Figure 11-18 Distribution pattern of carcinomas in situ involving both portio vaginalis and endocervical canal. (From Foote FW Jr, Stewart FW. The anatomical distribution of intraepithelial epidermoid carcinomas of the cervix. *Cancer* 1:431-440, 1948.)

P.304

Figure 11-19 Carcinoma in situ. (*Top*) Distribution of carcinomas in situ limited to portio vaginalis. (*Bottom*) Distribution pattern of carcinomas in situ limited to endocervical canal. (From Foote FW Jr, Stewart FW. The anatomical distribution of intraepithelial epidermoid carcinomas of the cervix. *Cancer* 1:431-440, 1948.)

P.305

Figure 11-20 Four illustrations that demonstrate how visual examination can give faulty impressions of the distribution or even the presence of carcinoma in situ of the cervix. The actual extent of the lesions is shown in red in the line drawings. Two of the cervixes have been painted with Lugol's solution. (From Foote FW Jr, Stewart FW. The anatomical distribution of intraepithelial epidermoid carcinomas of the cervix. *Cancer* 1:431-440, 1948.)

It has been known for many years that the prognosis of carcinoma of the uterine cervix depends on the stage of the disease. The current staging by the International Federation of Gynecologists (FIGO) is shown in Table 11-3. Stage I is subdivided into stage IA1 (no grossly visible tumor), stage IA2 (grossly visible and measurable tumor less than 1 cm in diameter) and stage IB, describing larger lesions confined to the cervix.

Any cancer of the cervix that extends beyond the anatomic boundaries of the surface epithelium or the basement membrane of the endocervical glands must be considered invasive.

Figure 11-21 The prevailing anatomic distribution of the three types of carcinoma in situ.

TABLE 11-3 STAGING OF CARCINOMA OF THE UTERINE CERVIX

Stage 0	Intraepithelial precancerous lesions (dysplasia, cervical intraepithelial neoplasia, low- and high-grade squamous intraepithelial lesions, carcinoma in situ)
Stage I	Carcinoma limited to cervix
	Stage IA - Invasive carcinoma identified microscopically
	IA1 - Microinvasive carcinoma (invasion <3 mm)
	IA2 - Microinvasive carcinoma not larger than 7 mm horizontally and 5 mm vertically*
	Stage IB - Lesion larger than stage IA2 whether or not visible
	IB1 <4 cm
	IB2 >4 cm
Stage II	Extension beyond the cervix (uterus, upper 2/3 of vagina, parametria)
	IIA - no obvious parametrial involvement

IIB - obvious parametrial involvement

Stage III Extension to pelvic wall or lower 1/3 of vagina

Stage IV **IVA** - extension to adjacent organs

IVB - metastatic spread

* Measured from base of epithelium, either surface or glands.

P.306

Invasion of the cervical stroma occurs in stages. The earliest stage of invasion is defined as **microinvasive carcinoma (stage IA), a lesion with invasion limited to 3 mm. Lesions with invasion greater than 3 mm must be considered as fully invasive cancer.** The histologic and cytologic patterns of these lesions are discussed in Part 2 of this chapter.

In actual practice, it is sometimes exceedingly **difficult to determine the anatomic boundaries on which the diagnosis of early invasion is based.** For example, the epithelium of the endocervical glands may be destroyed by cancer, leaving one quite helpless in deciding where the basement membrane of the glands is located. Precursor lesions occurring in squamous epithelium may produce “dips” surrounded by the basement membrane without actually invading the underlying stroma. Another difficulty may be due to inadequate sampling by biopsy and a precursor lesion may prove to be invasive in additional histologic material. Occasionally, the opposite is true: some distortion in the biopsy material may suggest invasion, whereas the surgical specimen will disclose only a precursor lesion. Studies of tenascin, a glycoprotein of the stroma of the uterine cervix, suggested an increased expression of this protein in microinvasive carcinoma (Iskaros and Koss 2000). **In debatable cases, as a rule of thumb, in the absence of clear-cut invasion in ample diagnostic material, the lesion may be considered as a precursor lesion and treated accordingly.**

The histologic and cytologic features of fully invasive cancer of the cervix are discussed in Part 2 of this chapter. Regardless of the histologic patterns and grade of invasive cancer, the **clinical stage of the disease is the most important prognostic yardstick.** In this respect, it must be noted that the errors in clinical staging may be considerable. Even with the availability of modern radiologic techniques, lymph node metastases may not be discovered prior to surgery. For example, among the 115 cases of Stage I cervix cancers, there were 19 cases (16.5%) with clinically unsuspected lymph node metastases (Sidhu et al, 1970).

HISTOLOGIC AND CYTOLOGIC TERMINOLOGY OF PRECURSOR LESIONS

Historical Overview

During the first half of the 20th century, all incidentally discovered intraepithelial lesions were universally known as “**carcinoma in situ**” or equivalent name and were treated by hysterectomy. As a consequence of cytologic screening and the first population studies conducted in the 1950s in the United States, it was noted that the precursor lesions differed from invasive cancer in several respects.

- The precursor lesions occurred generally in women several years younger than those with invasive cancer.
- The rate of discovery of the precancerous lesions was much higher than the calculated risk of developing invasive carcinoma in the same population, suggesting that not all of the precancerous lesions progressed to invasive cancer within the lifetime of the patient.
- Untreated precursor lesions did not necessarily progress to invasive cancer within a period of months or years.
- Some of the precancerous lesions “disappeared” (i.e., they could no longer be found in the uteruses removed after a biopsy that showed a precancerous lesion).
- There were marked cytologic and histologic differences among the various precursor lesions with regard to the degree of abnormality and cell configuration.

The Concept of “Dysplasia”

These observations led to attempts to separate, on cytologic and histologic grounds, the intraepithelial lesions with good prognosis (i.e., those unlikely to progress to invasive cancer)

from “true” precursors of cancer of the uterine cervix, i.e., **carcinoma in situ**. This resulted in the introduction of the term “**dysplasia**,” first suggested by a pathologist, William Ober, to Papanicolaou who used this term, in a paper published in 1949, to discuss lesions with low malignant potential. As the first results of follow-up of precursor lesions became available, James Reagan et al reintroduced, in 1953, the term **dysplasia or atypical hyperplasia** to describe biopsy-documented precursor lesions with benign, or at least noninvasive, behavior. For purposes of comparison, Reagan selected carcinomas in situ made up of small cells. All carcinomas in situ were treated but the “atypical hyperplasias” were followed. The conclusions of this paper were carefully worded and reflected considerable diagnostic uncertainty. Although 35 of 65 lesions classed as “dysplasia” or “atypical hyperplasia” disappeared, many after biopsies, the remaining lesions remained unchanged, and one progressed to invasive cancer. Subsequent writings by Reagan and his colleagues, notably Stanley Patten (1962), further emphasized the **concept of dysplasia as a neoplastic intraepithelial lesion of uncertain prognosis, to be contrasted with carcinoma in situ, an obligate precursor of invasive cancer**. Patten (1978) subdivided dysplasia into three types: **keratinizing (pleomorphic), nonkeratinizing, and metaplastic**, each category further subdivided into **mild, moderate, and severe**.

The concept of **dysplasia** suggested that there are **two categories of intraepithelial lesions** in the uterine cervix: **carcinoma in situ**, an obligate precursor lesion of invasive cancer of the cervix, and **dysplasia**, an ill-defined but essentially “less malignant” abnormality.

The diagnostic system **dysplasia-carcinoma in situ** was formalized in 1962 as “An International Agreement on Histological Terminology for the Lesions of the Uterine Cervix,” published in *Acta Cytologica* 6:235-236, 1962. The following definitions were offered:

“*Carcinoma in Situ*: Only those cases should be classified as carcinoma *in situ* which, in the absence of invasion, show as surface lining an epithelium in which, throughout its whole thickness, no differentiation takes place.”

“*Dysplasia*: All other disturbances of differentiation of

P.307

the squamous epithelial lining of surface and glands are to be classified as dysplasia. They may be characterized as of high or low degree....”

Many observers, including the famous surgical pathologist, Arthur Purdy Stout (1957) and this writer (1978), **objected to these definitions** as entirely too narrow, particularly in reference to the claim that any lesion that showed surface differentiation was a “dysplasia” and not a carcinoma in situ and, therefore, was not capable of invasion. Nonetheless, the term “dysplasia” proved nearly irresistible to the practicing pathologists and gynecologists who embraced it with enthusiasm. The advantage of this term was quite apparent: for pathologists, the term was vague enough to lift the burden of establishing a diagnosis of a carcinoma in situ, then requiring immediate treatment, and for the gynecologists, it provided a choice of therapies ranging from “do nothing” to hysterectomy, with a number of intermediate procedures. In fact, as precursor lesions were being observed **in organs other than the uterine cervix**, the term **dysplasia** was also adopted to describe these lesions.

It has been the assumption of many clinicians that the pathologists were able to distinguish among the various levels of dysplasia and separate these lesions from carcinoma in situ, and that this distinction was of prognostic value. This assumption is not accurate. Several diagnostic surveys documented lack of consistency among knowledgeable pathologists in the classification of precursor lesions of the cervix (Siegler, 1956; Cocker et al, 1968; Seybolt and Johnson, 1971; Ismail et al, 1989, 1990; Robertson et al, 1989). It has been recently proposed that **typing for human papillomavirus (HPV) may serve as an aid to classification of precursor lesions** (Sherman et al, 1994; Crum et al, 1997). Although the results of these studies, besides their cost, are not fully persuasive, the issue is not without merit and it is further discussed in Part 2 of this chapter.

The Concept of Cervical Intraepithelial Neoplasia

Follow-up studies by Richart and Barron (1969) confirmed the views previously expressed by Koss et al (1963) that, regardless of morphologic appearance, all precancerous intraepithelial abnormalities of the uterine cervix are capable of progression to invasive cancer, albeit with a low frequency for the better differentiated (low-grade) lesions and a higher frequency for poorly differentiated (high-grade) lesions. Richart suggested the name **cervical intraepithelial neoplasia (CIN)** for these lesions. In order to satisfy the requirements of cytologic and histologic reporting, Richart initially suggested that the lesions be graded from I to IV. Grade I corresponded to morphologically lesser lesions and grade IV to classic carcinomas in situ. Subsequently, **the number of grades of CIN was reduced to three, and still more recently to two, “low-grade” and “high-grade” CIN** in keeping with the Bethesda System of

nomenclature, to be discussed below.

Cytologic Nomenclature

Papanicolaou's Classes

The initial classification of cervicovaginal smears was proposed by Papanicolaou who formulated a series of guidelines of smear interpretation in **five classes**:

- Class I.** Absence of atypical or abnormal cells.
- Class II.** Atypical cytology but no evidence of malignancy.
- Class III.** Cytology suggestive of, but not conclusive for, malignancy.
- Class IV.** Cytology strongly suggestive of malignancy.
- Class V.** Cytology conclusive for malignancy.

The system of classes was generally well received and it is still in use in many laboratories in many countries, although the significance of "classes" was often modified to fit the requirements of the laboratories in their contacts with clinicians. Papanicolaou himself was not fully satisfied with the system, particularly with Classes II and III, because they offered little diagnostic flexibility. In the years 1952-1958, when this writer had the privilege of working with him, Papanicolaou used plus and minus signs, added to the class, to express more precisely his diagnostic opinion. For example, Class II +, or III- were used to define cervicovaginal smears. To my knowledge, Papanicolaou has never published these observations.

The Bethesda System

With the passage of time, it became apparent that the histologic and cytologic nomenclatures should be similar, if not identical, to facilitate the exchange of information among investigators and laboratories. Starting with the first edition of this book (1961), it was advocated that cytologic diagnosis should reflect, whenever possible, the histologic nature of the underlying lesions. In December 1988, a committee of experts, convened under the auspices of the National Cancer Institute (United States) in Bethesda, Maryland, proposed a system of diagnostic guidelines for the interpretation of the cervicovaginal smears.

The Bethesda System (modified in 2001) was officially accepted by the federal authorities in the United States in a series of rules governing the performance of the laboratories and incorporated in 1988 into the amendment to the Clinical Laboratory Improvement Act (**CLIA 88**), passed by the United States Congress (for the complete text of the Bethesda System, see Appendix at the end of Part 2 of this chapter). Several features of the Bethesda System will be discussed elsewhere in this book. **The cytologic features of the precursor lesions of squamous carcinomas of the uterine cervix were divided into two groups:**

- **Low-grade squamous intraepithelial lesions (LGSIL)**, corresponding to histologic patterns in which the fundamental structure of the epithelium of origin (usually the squamous epithelium) is reasonably well preserved (see Fig. 11-14). LGSIL includes, under the same umbrella, lesions variously known as mild or slight dysplasia, flat condylomas, CIN I, with or without features of condyloma.
- **High-grade squamous intraepithelial lesions (HGSIL)**, corresponding to histologic lesions in which the epithelium of origin is replaced by highly abnormal smaller cells. HGSIL includes lesions variously known as moderate and severe dysplasia and carcinoma in situ, CIN II, III (see Figs. 11-16 and 11-17).

P.308

TABLE 11-4 COMPARATIVE CYTOLOGIC AND HISTOLOGIC NOMENCLATURE OF PRECURSOR LESIONS AND SQUAMOUS CARCINOMA OF THE UTERINE CERVIX

	No evidence of disease	Atypia not further defined	Low-grade lesions	High-grade lesions	Invasive cancer
Papanicolaou	Class I	Class II	Class III	Class IV	Class V
The Bethesda System	Within normal limits	ASC-US AGUS	LGSIL	HGSIL	Cancer

Reagan and Patten	Mild dysplasia *	Moderate and severe dysplasia, carcinoma in situ	Cancer
Richart original	CIN I	CIN II and III	Cancer
Richart modified	CIN low grade	CIN high grade	Cancer

* AGUS is no longer recommended (see Part 2 of this chapter).

This binary system of smear classification, which is consistent with the developments in histologic nomenclature, proved to be easier to use and is probably better reproducible than other diagnostic approaches.

Table 11-4 summarizes the prevailing classification systems of precursor lesions of the uterine cervix.

FOLLOW-UP STUDIES OF PRECURSOR LESIONS OF CARCINOMA OF THE UTERINE CERVIX

Recent observations on the role of human papillomavirus in the genesis of cervical cancer, several of which were cited above, have led to a number of follow-up studies of untreated precursor lesions in the belief that HPV typing may provide a better guide to behavior of these lesions than morphologic assessment. Such studies, that may put the lives of patients into serious jeopardy, have been undertaken with limited, if any, regard of past experiences with these lesions. For this reason, a summary of "old" studies is provided for the interested reader. These studies, which were conducted without the "informed consent," either because it was not required or because the investigator did not believe in the malignant potential of precursor lesions, could not be implemented today because of risk to patients.

Earliest Studies

The concept of carcinoma in situ as a precursor lesion of invasive cervical cancer received initial support from comparative histologic studies of patterns of invasive carcinoma and the surface alterations of the epithelium accompanying invasive cancer (Schauenstein, 1907). In fact, in suitable histologic material, the invasive component of superficially invasive carcinomas can always be traced to the surface epithelium which may vary in appearance and occasionally shows only trivial abnormalities rather than a high-grade precursor lesion. Additional support for the role of carcinoma in situ as a formative stage of cervical cancer was received from observations made prior to 1952. Several dozen cases were published in which biopsies of the uterine cervix, obtained anywhere from 2 to 16 years prior to the occurrence of invasive carcinoma, showed patterns of carcinoma in situ (summary in Stoddard 1952).

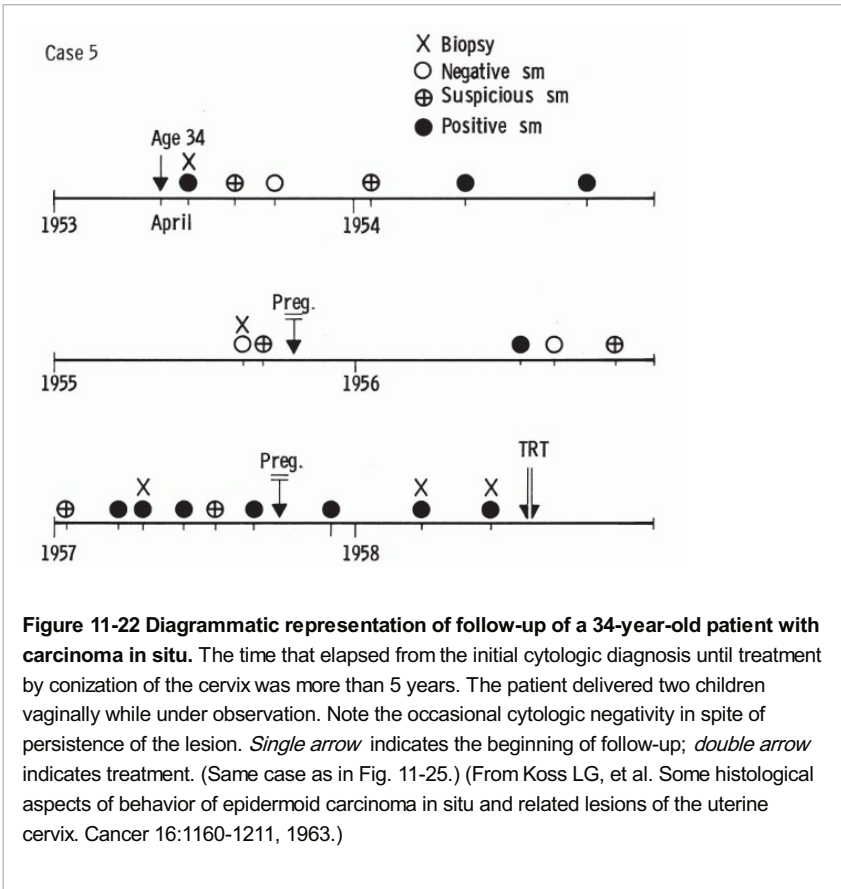

Prospective studies of precursor lesions of the uterine cervix carry with them substantial risk to the health of patients because of the danger of developing invasive carcinoma. Therefore, some of the most important data were accumulated during the 1950s and early 1960s before the threat to patients was fully understood. Thus, in the Abraham Flexner lecture of 1953, the well-known Swedish gynecological radiotherapist, Dr. Hans L. Kottmeier, said this about carcinoma in situ of the uterine cervix: "Many surgeons and gynecologists are of the opinion that patients having so-called carcinoma in situ should always be referred for treatment. This has not been proved." In support of his doubt, Kottmeier presented a series of 59 patients with carcinoma in situ, followed at the Radiumhemmet in Stockholm without treatment. At the time of the Flexner lecture, only eight of these patients (13.5%) had developed invasive carcinoma after 2 to 10 years of observation. With the passage of time, Kottmeier was forced to change his mind. In a personal communication (to LGK), dated August 2, 1968, he stated that, out of a group of 34 patients with untreated carcinoma in situ, followed for periods of 20 years or more 25 (73%) developed invasive cancer of the cervix. Three patients developed invasive carcinoma within less than two years and possibly the lesion had been overlooked on initial examination. In the remaining 22 patients, invasive cancer was observed after a follow-up period varying from 5 to 21 years.

Another classical series of observations was published by Petersen of Copenhagen (1955), who shared Kottmeier's

doubts as to the significance of intraepithelial precursor lesions. In a remarkable study stretching over a period of more than ten years, Petersen was able to follow, without major treatment 127 women whose cervical biopsies disclosed lesions classified into two groups, as “epithelial hyperplasia with nuclear abnormalities” and “borderline cases.” Although the supporting photographic evidence is scanty, it appears that Petersen's group of “epithelial hyperplasia with nuclear abnormalities” represented low-grade lesions in which the features of cancer were not well developed; in the group designated by him as “borderline cases,” the lesions probably would have been classified today as a high-grade lesion (CIN III or carcinoma in situ). Yet, 34 patients (26.8%) from both groups, developed invasive cervix cancer with only a slight percentile preference for the more abnormal patterns. Petersen also documented that not all of the lesions progressed to carcinoma; at the end of three years of observation the abnormal epithelium apparently disappeared in 30 patients and remained stationary in 50 patients, regardless of the initial biopsy findings. It is also worth emphasizing that Petersen did not consider superficial electrocautery leaving no visible scars, or application of silver nitrate to the cervix as treatment, although these procedures may have contributed to the regressions of some of the lesions. Petersen concluded the paper by stating that **“the methods used (histological assessment of biopsies of the cervix) have not been able to distinguish ‘genuine’ from ‘false’ precancerosis.”**

Another study from Copenhagen by Lange (1960), later updated by Sorenson et al (1964), gave similar results: 18 of 83 patients (22%) with “epithelial hyperplasia with nuclear abnormalities” (or low-grade lesions), and 6 of 17 (35%) “borderline cases” (or high-grade lesions), developed invasive carcinoma within five years.

These initial studies provide ample evidence that **some high-grade lesions, such as carcinomas in situ, but also lower grade precursor lesions, if untreated, will progress to invasive carcinoma of the uterine cervix in a substantial proportion of patients and that the risk to the patients increases with the passage of time.** On the other hand, it became equally evident that **some of these lesions will either regress without treatment or persist without changes.** Because of poor histologic documentation, the older studies shed limited light on the prognostic value of various histologic patterns encountered in the precursor lesions. This led to the Memorial Hospital study, supervised by competent pathologists, which is summarized below.

Personal Observations on Behavior of Untreated Precursor Lesions

In a prospective study of carcinoma in situ and related lesions conducted at the Memorial

Hospital for Cancer (now the Memorial-Sloan Kettering Cancer Center) between 1952 and 1963, 93 patients with precancerous lesions of the cervix were followed without treatment for periods ranging from seven months to eleven years (Koss et al, 1963). A few patients with untreated lesions, observed prior to 1952, were also included in the study. At the onset of the study, all patients were asymptomatic and of childbearing age. The lesions, detected by cytology, were classified into two groups according to the degree of **histologic abnormality**: the **group of "carcinoma in situ,"** comprising classical carcinomas in situ and lesions with various degrees of surface maturation that other observers could classify as moderate or severe dysplasia. The second **group of "borderline lesions"** comprised epithelial abnormalities that would be classified today as "low-grade." The emphasis in the study was on a minimum of disturbance of the cervical lesions; therefore, cytology was used extensively as a method of follow-up after the initial diagnosis was established by biopsy. Additional biopsies were obtained only if there was a clinical or cytologic indication that the lesion was changing in character (Fig. 11-22). Douches and vaginal

P.310

tetracycline or trichotone (an antiparasitic agent) suppositories were used in some patients as the only interim treatment. If there was any clinical, histologic, or cytologic suspicion of a possible invasion, or if the lesion showed no signs of regression after several years of follow-up, the patients were treated by hysterectomy.

TABLE 11-5 PATTERNS OF BEHAVIOR OF LESIONS OF CERVICAL EPITHELIUM

Behavior	Carcinoma in Situ		Borderline Lesions		Total	
	No.	%	No.	%	No.	%
Disappeared*	17	25.4	10	38.5	27	29
Persisted	41	61.2	4	15.4	66	71
Progressed to carcinoma in situ	0		11	42.3		
Progressed to questionable invasion	5	7.5	0			
Progressed to invasive carcinoma	4	5.9	1	3.8		
Total	67		26		93	

* See Table 11-6.

(Koss LG, et al. Some histological aspects of behavior of epidermoid carcinoma in situ and related lesions of uterine cervix. A long-term prospective study. Cancer 16:1160-1211, 1963.)

Sixty-seven patients with high-grade lesions and 26 patients with low-grade lesions were evaluated. The observations are summarized in Tables 11-5 and 11-6.

High-Grade Lesions

In spite of all the precautions outlined above, four of the patients with carcinoma in situ developed superficial but frank invasive cancer after 16 months to 4½ years of follow-up. In an additional five patients, the possibility of microscopic invasion could not be ruled out in serial sections because the lesions produced "dips" into the stroma. The lesions remained relatively stationary in 41 patients for periods varying from one to ten years. Often, however, **there were significant changes in the histologic appearance of the lesion.** The changes were unpredictable and suggested either an increase or a decrease in the degree of abnormalities. Corresponding changes were noted in smears (Fig. 11-23). Seventeen of the 67 patients, or one quarter, showed total regression of the lesion, documented by a negative cytologic follow-up of at least three years' duration. Shorter follow-up proved unreliable and lesions were observed that "recurred" after an "absence" of two years.

TABLE 11-6 DISAPPEARING LESIONS

	Carcinoma in Situ	Borderline Lesions
Biopsy	6	7
Terramycin	7	2
Trichotone	2	0
Spontaneous	2	1
Total	17	10

(Koss LG, et al. Some histological aspects of behavior of epidermoid carcinoma in situ and related lesions of uterine cervix. A long-term prospective study. Cancer 16:1160-1211, 1963.)

An analysis of the effects of the biopsies suggests that **even a small biopsy may cause a regression of a focus of carcinoma in situ** (Figs. 11-24 and 11-25). It is unlikely that the biopsies, per se, removed the entire lesion, particularly when it was present in two or more quadrants of the cervix. It appears more reasonable to assume that regenerating epithelium may dislodge and replace fragments of abnormal epithelium (Fig. 11-26). It is also evident that **new lesions may develop in adjacent, previously normal areas of the cervical epithelium**, as shown in Figures 11-24 and 11-25. It is of note that, **in some patients, the regression of the lesion occurred after treatment with vaginal suppositories of tetracycline and Trichotone**, possibly because of a desquamative effect of these drugs on the cervical epithelium.

Borderline or Low-Grade Lesions

Of the 26 patients with a low-grade (borderline) lesion 11 developed a high-grade lesion 4 remained stationary, and 10 lesions regressed, either spontaneously or following biopsies or vaginal suppositories. It was assumed that, because of their exposed position on the surface of the cervix, these lesions were generally easier to eradicate than carcinoma in situ. One patient, who refused therapy, developed an invasive cancer 13 years after biopsy (Fig. 11-27).

It must be stressed that **cytology was not always reliable** as a tool of follow-up. As shown in Figure 11-22, negative smears were observed repeatedly throughout the follow-up period even though in some patients there was synchronous biopsy evidence that the lesion was present in the cervix epithelium at the time the smear was obtained. Thus, **this study casts serious doubt on the reliability of the smears as a follow-up procedure.**

P.311

Figure 11-23 Carcinoma in situ. Initial biopsy (A) and smear (B) of a carcinoma in situ. Note the anaplastic appearance of the lesion. C. Appearance of a cervix biopsy 2 years later. Note that there is less anaplasia and that the surface is much better differentiated. D,E. Appearance of the smear and of the surgical specimen obtained 4½ years after the initial biopsy. The lesion was superficially invasive and yet better differentiated than the initial biopsy. This change was reflected in the smear.

P.312

Pt. C.M.

Figure 11-24 Diagrammatic representation of serial biopsies of the cervix obtained on a 39-year-old patient. By careful designation of the areas of the biopsy, it was possible to ascertain the effect of biopsies on carcinoma in situ. Each square represents a biopsied area; the black squares represent biopsies with carcinoma in situ. Note that the 12-o'clock area, which showed tumor on the initial biopsy, was "cured" 11 months later; at that time the tumor appeared in the 6-o'clock area. Six months later the tumor was present in the 3-, 9-, and 12-o'clock areas but had disappeared from the 6-o'clock area. At the time of conization 9 months later, the tumor had regrown in all four quadrants of the cervix.

These studies clearly established that, **under uniform conditions of observation, the level**

of histologic abnormality of the intraepithelial precancerous lesions may vary with the passage of time and is of limited prognostic value. Lesions classed either as high-grade or as low-grade, hence the entire histologic spectrum of lesions comprising the cervical intraepithelial neoplasia, **disclosed a capricious and unpredictable behavior that was significantly influenced by minor diagnostic or therapeutic procedures.** Sufficient numbers of these lesions, regardless of epithelial make-up, progressed to invasive carcinoma, **confirming the potentially malignant nature of all precursor lesions.** Of signal importance, in view of the current trends to consider low-grade lesions as innocuous, was the progression of these lesions to higher grade of intraepithelial abnormalities or, in a patient lost to follow-up for several years, to invasive cancer.

Pt. E. B.

Figure 11-25 Diagram representing the shifting position of carcinoma in situ after biopsies. This patient was 34 years old at the time of the initial biopsy and succeeded in establishing a family while under observation (see diagram in Fig. 11-22). Note especially that the last biopsy obtained shortly before conization removed most of the tumor so that only a small area of carcinoma in situ was noted in the cone. There was no trace of cancer in the 6- and 9-o'clock areas of the cone as was observed in the first set of biopsies.

Other Studies

A confirmation of the conclusions of the personal studies summarized above was provided by Richart (1967) who followed, by cytology and colpomicroscopy, a group of 557 women with varying degrees of "dysplasia" for an average period of 36 months. Admission to the study was based on three consecutive abnormal smears; hence, these patients may have represented a select population of women at risk. The study was interrupted after three patients with "mild dysplasia" developed invasive carcinoma. Only 6% of the lesions disappeared spontaneously. In the remaining patients, the lesions either persisted without change or progressed to higher levels of dysplasia and, in 18 women, to carcinoma in situ. **The patterns of cytologic or histologic abnormalities was of no prognostic value, even among the low-grade lesions (mild dysplasia), which led Richart to the conclusion that all of these lesions constitute a spectrum of abnormalities for which the term cervical intraepithelial neoplasia (CIN) was suggested (see above).**

Important evidence in the assessment of "dysplasia" and, hence, lesions with only slight or moderate abnormalities as a step in the genesis of carcinoma of the cervix, was provided by Stern and Neely (1963). In 94 cases of dysplasia, the rate of new carcinomas in situ was 106 per 1,000 (as compared with the new population rate of 5.1/1,000), and the rate of invasive carcinoma was 11 per 1,000 (compared with the new population rate of 1.5/1,000). In a subsequent study (1964), these same authors observed that **women with dysplasia had a 1,600 times greater chance of developing carcinoma in situ and 100 times greater chance of developing invasive cancer than women without disease of the cervix epithelium.**

There are two much cited Swedish studies on mild and moderate dysplasia (Nasiell et al, 1983, 1986). In the 555 women with mild dysplasia, followed without treatment for up to 12 years (mean follow-up 39 months), 342 lesions (62%) regressed; 122 lesions (22%) persisted unchanged; 91 lesions (16%) progressed to severe dysplasia or carcinoma in situ; and 2 progressed to invasive cancer. The 2 invasive cancers were observed in women who failed to appear for a follow-up examination (Nasiell et al, 1986). Biopsies, performed in 76 patients (14%), failed to influence the outcome. The regression was observed in 167 women for more than 1 year and in 175 women for less than 1 year. The behavior of the lesions was not age related. In a study of 894 women with moderate dysplasia, followed without treatment for up to 12 years (mean 78 months) and reported in 1983 (Nasiell et al, 1983), the lesions disappeared in 483 patients (54%), persisted unchanged in 140 patients (16%), and progressed to

carcinoma in situ and beyond in 271 patients (30%). In the last group, 3 developed invasive cancer. In this group of patients, biopsies contributed to regression of the lesions. In patients age 51 or older, fewer lesions progressed and the time of progression was longer than in younger women. These authors observed long periods of negative cytology in many of the patients with persisting or progressing lesions. Nasiell et al (1983) estimated the risk of carcinoma in situ or invasive cancer for patients with mild dysplasia at 500 times and for

P.313

patients with moderate dysplasia at 2,000 times greater than for women without lesions. These studies are summarized in Figure 11-28.

Figure 11-26 Schematic representation of a possible mechanism involved in eradication of areas of carcinoma in situ (in black). It is assumed that fragments of residual carcinoma in situ may be cast off during the inflammatory and reparative processes following biopsy. (From Koss LG, et al. Some histological aspects of behavior of epidermoid carcinoma in situ and related lesions of the uterine cervix. *Cancer* 16:1160-1211, 1963.)

A number of other reports are summarized in Table 11-7. Varga (1966), reporting a follow-up study of 78 untreated patients with dysplasia, observed carcinoma in situ in 39 of them and invasive carcinoma in 11. Thus, progression of "dysplasia" to an identifiable form of cancer was observed in 64% of patients, one of the highest figures reported. Villa Santa (1971) reported on two groups of patients with an initial diagnosis of "dysplasia" established on punch biopsies of the cervix. In a group of 297 patients in whom immediate conization of the cervix was performed, the tissue study revealed carcinoma in situ in 66 patients (22.2%), microinvasive carcinoma in 12 patients (4%), and fully invasive carcinoma in 7 patients (2.4%). There was an additional group of 63 patients in whom, for various reasons, conization was delayed for periods from 2 to 115 months. In this group 10 patients (15.8%) developed carcinoma in situ and 13 patients (20.6%) invasive carcinoma, 3 of which were microinvasive.

Figure 11-27 A borderline lesion of the cervix observed in a biopsy obtained in 1946 because of “abnormal smear.” A. Note the nuclear abnormalities and the very satisfactory epithelial stratification. This patient refused treatment and was seen elsewhere 13 years later with a frank invasive carcinoma of the cervix (B). (B: Courtesy of Dr. Harry Zimmerman, New York, NY.)

P.314

Figure 11-28 Results of long-term follow-up without treatment and probability of progression of 894 patients with moderate dysplasia (A) and 555 patients with mild dysplasia (B) of the uterine cervix epithelium. In A, the probability of progression of moderate dysplasia (CIN II) to CIN III or invasive carcinoma is approximately 30% for all patients and somewhat higher (about 35%) for the 410 patients observed without biopsies. In B, the probability of progression is only slightly less for the patients with mild dysplasia (CIN I). Apparently, cervix biopsies had no impact on this group of women. (A: Redrawn from Nasiell K, et al, 1983. B: Redrawn from Nasiell K, et al, 1986.)

Gad (1976), in a small but important study, reported follow-up data on 13 patients with “severe dysplasia” and 17 patients with carcinoma in situ, not treated except for initial biopsy. Two of the 13 patients with severe dysplasia and 7 of the 17 patients with carcinoma in situ developed invasive cervical cancer, and 2 died of the disease.

In a study of severe dysplasia (Westergaard and Norgaard, 1981), progression to carcinoma in situ and invasive carcinoma was observed in 57% of 49 patients who underwent biopsy but were otherwise untreated, whereas no recurrent disease was observed in 38 patients treated by conization.

The results of a long-term follow-up study of a cohort of 2,279 patients with cytologic “dyskaryosis” and, hence, precursor lesions below the level of carcinoma in situ, were provided as a personal communication by David Boyes of Vancouver, British Columbia, Canada, where

one of the best cervix cancer prevention programs was instituted in 1950. A spontaneous regression of the cytologic abnormalities was observed in 32% of patients. Among 1,550 patients with persisting cytologic abnormalities, 44% developed carcinoma in situ, and 5% developed invasive carcinoma of the uterine cervix.

Two other important studies were performed in the United Kingdom. In 1978, Kinlen and Spriggs could trace 52 British patients with abnormal smears who had neither a biopsy nor further treatment. After several years (mean 5.2 years), 19 patients were found to be free of lesions, 20 patients had some form of precancerous lesion ("dysplasia" or carcinoma in situ) on biopsy, 3 patients developed a microinvasive carcinoma, and 10 had fully invasive cancer. In a subsequent paper, Spriggs and Boddington (1980) reviewed the smears of 28 of these patients, 17 with regression and 11 with progression to invasive cancer. They supplemented this small series with 35 smears from untreated patients from the files of their laboratory, 25 of whom "regressed" and 10 of whom "progressed" to invasive cancer. The review of the cytologic material revealed that, in patients whose lesions regressed, the dominant smear pattern was that of low-grade lesions (mild dysplasia, CIN I). Of 36 women with smear patterns suggestive of high-grade lesions (CIN II, III), 15 regressed and 21 progressed to invasive cancer. The average rate of invasive cancer in the eligible patient groups listed in Table 11-7 was 4.4%.

Additional important data on the natural history of carcinoma in situ were the result of skepticism as to the true nature of this disorder in New Zealand (Green 1969, 1970; Green and Donovan, 1970). The results of 5 to 28 years follow-up of a cohort of 948 women with biopsy-documented carcinoma in situ, but no further treatment, were described by McIndoe et al (1984). A great many of these women had a "cone biopsy" of the cervix either at the onset or during the follow-up period. The patients were divided into two groups; there were 817 patients with "normal" cytologic follow-up and 131 patients with continuing cytologic abnormalities. Twelve patients in the first group (1.5%) and 29 patients in the second group (22%) developed invasive cancer either of the cervix or of vaginal vault. Thus, diagnostic conization did not prevent the development of invasive cancer.

The unfortunate results of this study created a great deal of upheaval and led to the introduction of strict guidelines of cervix cancer detection and treatment in New Zealand (Jones, 1991).

Östör (1993) performed a meta-analysis based on a large number of follow-up papers and concluded that for CIN I, the cumulative rate of regression was 57%, rate of persistence 32%, rate of progression to CIN III was 11%, and to invasive cancer 1%. The figures for CIN II were: regression 43%, persistence 35%, progression to CIN III 22%, and to invasive cancer 5%. The figures for CIN III were: regression 32%, persistence 56%, and progression to invasive

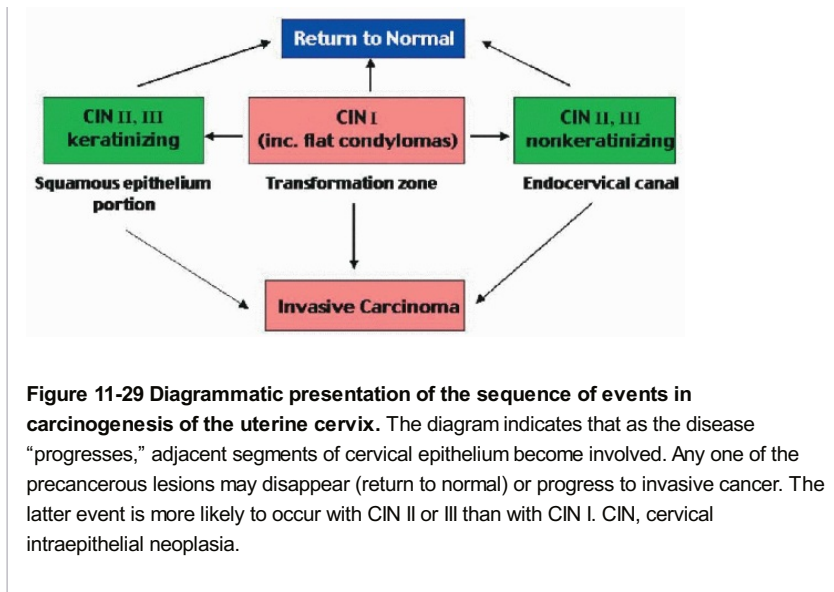

P.315

cancer about 12%. Unfortunately, in this study, as in many other studies of precursor lesions, the precise diagnoses could not be verified.

TABLE 11-7 EARLY STUDIES ON BEHAVIOR OF PRECURSOR LESIONS FOLLOWED WITHOUT TREATMENT								
Author/year	Type of lesion	No. of pts.	Duration of follow-up	Regression	Persistence	Progression to high-grade lesions	Development of inv. ca	Comments
Varga 1966	"Dysplasia"	78	Several yrs.			39 (50%)	11 (14.1%)	
Richart 1967	"Mild dysplasia"	557	3 yrs.	33 (6%)			3 (0.5%)	Study interrupted as dangerous to patients

‡ Personal communication.								

Although there are some important numerical differences among the studies cited, they all confirm the basic behavior patterns of the precursor lesions. **Regardless of grade of abnormality, these lesions may regress, remain the same, or progress to invasive cancer.** A diagrammatic summary of these events is shown in Figure 11-29. Although low-grade lesions are more likely to regress and less likely to progress to CIN III or invasive cancer than high-grade lesions, their presence puts the patients at a significant risk for future neoplastic events, including invasive cancer. These observations are particularly pertinent because of current recommendations that allow for conservative follow-up of low-grade lesions (Kurman et al, 1994). It still remains to be documented, by a long-term prospective study, whether the presence of high-risk human papillomavirus is the main factor accounting for the behavior of precancerous lesions, as has been advocated by some observers (see above). **Conservative follow-up of precursor lesions, regardless of grade, should never be done unless the patient is fully and carefully informed about the risks and perils of this approach.**

THE SEARCH FOR OBJECTIVE PROGNOSTIC PARAMETERS IN PRECURSOR LESIONS

The unpredictable behavior of precursor lesions of cancer of the uterine cervix has led to a large number of studies to predict the future behavior of these lesions.

Human Papillomavirus Typing

This issue was discussed at length above in reference to human papillomavirus. Briefly, persistent infection with a high risk virus is considered a risk factor for high-grade intraepithelial lesion and, by implication, invasive cancer of the uterine cervix. The practical considerations of HPV typing will be discussed in Part 2 of this chapter.

Immunocytochemistry

Blood Group Antigens

Davidsohn and Kovarik (1969), using a red cell adherence test, observed that the blood group isoantigens A, B, H, present in the normal epithelia, cannot be detected in carcinomas of the uterine cervix. The loss of isoantigens was progressive from “dysplasia” to carcinoma in situ to invasive and metastatic carcinoma, as evidence of progressive tumor dedifferentiation. These results were confirmed by Bonfiglio and Feinberg (1976) but not by Lill et al (1976). Lindgren (1986), using monoclonal antibodies, observed a relationship of **blood group antigen expression to 5 year survival and, hence, prognosis**, which was better in the antigen-positive group than in the antigen-negative group. As the interest in the expression of blood group antigens waned, there have been no recent studies on the clinical value of this approach.

Other Antigens

With the use of cytochemical and histochemical techniques (see Chapter 45), a number of tumor markers and embryonic antigens were studied in cervical cancer and its precursors. Thus, the presence of **carcinoembryonic antigen (CEA)** and its distribution in tissue were studied, among others, by van Nagell et al (1982) and Bychkov et al (1983). The CEA was expressed by a large proportion of precancerous lesions and invasive epidermoid carcinomas and by all endocervical adenocarcinomas. **Alpha-fetoprotein (AFP)** expression was seen by Bychkov in only one case of a glassy carcinoma (see Chapter 12). **Human chorionic gonadotropin (hCG)** was not expressed by any of the precancerous lesions or carcinomas studied by Bychkov. Epithelial membrane antigen (**EMA**) is strongly expressed by abnormal squamous cells from precancerous lesions, as reported by Moncrieff et al (1984).

Oncogenes

Oncogene expression in invasive carcinoma was studied with an antibody to p21 **ras oncogene** product by Sagae et al (1989) and Hayashi et al (1991). The studies were of limited prognostic value. **p53 mutation** was observed as a late event in cervical cancer of no prognostic value (Bremer et al, 1995). The expression of p63 (a homologue of p53) was studied in a wide variety of cervical cancers (Wang et al, 2001). Nearly all squamous cell carcinomas were strongly positive for this protein, whereas adenocarcinomas and a subset of neuroendocrine carcinomas were negative. A number

of genes involved in **apoptosis** have been studied in cervical cancer precursors and in invasive cancer but the published data are contradictory and do not appear to be of prognostic value at this time. Studies of **erbB-2** expression had limited value (Hale et al, 1992). **Epidermal growth factor** expression was studied by several observers with debatable results (Berchuk et al, 1990; Chapman et al, 1992).

Loss of retinoblastoma (Rb) gene was a common event in small-cell carcinomas of cervix (Harrington et al, 1999). The finding did not correlate with type of HPV, even though the interaction of E7 protein of HPV16 with Rb gene has been repeatedly confirmed (Boyer et al, 1996; Chetty et al, 1997).

Further possibilities of molecular studies have been suggested by Chuakai et al (1999) who documented that mRNA of good quality can be extracted from cells in archival cervicovaginal smears.

DNA Synthesis and Proliferation Indices

Studies with tritiated thymidine, a labeled precursor of DNA, carried out by Moricard and Cartier (1964), pointed out that DNA synthesis in normal squamous epithelium is confined to the basal layer, whereas, in neoplastic epithelium, evidence of DNA synthesis may be found throughout the epithelial thickness. Similar studies conducted by Rubio and Lagerlöf (1974) on various precursor lesions documented that low-grade lesions showed less DNA synthesis than classic carcinoma in situ. These observations were confirmed in more recent times by other techniques. Al-Saleh et al (1995) reported that the distribution of **nuclear proliferation antigens, Ki-67**, was confined to the basal layers in normal and metaplastic epithelium. In low-grade precursor lesions, the nuclear proliferation was also seen in intermediate epithelial layers, but some overlap occurred with squamous metaplasia. In high-grade precursor lesions, however, the antigen expression could be observed throughout the epithelial thickness. The density of Ki-67 expression was higher in lesions associated with intermediate- and high-risk HPVs than in lesions associated with the low-risk HPVs, types 6 and 11. Using the **proliferating cell nuclear antigen (PCNA)**, Mittal et al (1993) reported similar results.

Because HPV interferes with cell cycle (see above), Keating et al (2001) studied the expression of **cell-cycle-associated proteins** as surrogate biomarkers. **Ki67, cyclin E, p16^{INK4}** were assessed by immunochemistry. The study had for its purpose a clarification of criteria for cervical lesions ranging from metaplasia to HGSIL because of diagnostic disagreements among the participating expert pathologists. Although predictably higher staining levels were associated with HGSIL than other lesions, several of the benign lesions also had weak expressions of these proteins. In spite of an enthusiastic endorsement of these costly and cumbersome techniques by the authors of this paper, their practical value requires further studies.

Skylberg et al (2001) studied aberration of centrosomes in CIN lesions by immunofluorescence to **tubulin**, the enzyme necessary for formation of mitotic spindle. An **increased number of centrosomes** (predictive of abnormal mitoses) was observed in LGSIL, HGSIL, and invasive cancer when compared with normal epithelium.

Predictably, **mitotic counts** also indicated that the frequency of mitoses is higher in high-grade than in low-grade lesions (Tanaka, 1986). Further, the presence of **abnormal mitotic figures** was common in lesions associated with HPV 16 (Crum et al, 1984). There is no evidence that these observations can be used for prognostic purposes.

Telomerase expression was found to be universal in neoplastic lesions but confined to the basal layers in normal epithelium (Frost et al, 2000).

Along similar lines, Williams et al (1998) used **antibodies to proteins regulating DNA replication** to recognize cancer cells in cervicovaginal smears.

DNA Quantitation

Early studies by Mellors et al (1952), Reid and Singh (1960), Atkin (1964), O. Caspersson (1964), Sandritter (1964), and others demonstrated, by microspectrophotometric methods, that many (but not all) cells derived from precursor lesions of carcinoma of the cervix show increased DNA content. Subsequently, other techniques, such as Feulgen cytophotometry and flow cytometry were used on histologic and cytologic material in the search for data of prognostic significance. The results of numerous studies were contradictory and failed to produce data of value (Brandão, 1969; Grundmann et al, 1961; Sacks et al, 1972). The likely reason for the inconsistency of the results was demonstrated by Fu et al (1981), who showed that precursor lesions could be either diploid, polyploid, or aneuploid. Fu postulated that the aneuploid lesions (regardless of grade) were more likely to persist or progress, but the significance of this observation has not been independently confirmed. Perhaps the most

significant of these studies was presented by Hanselaar et al (1988), who studied DNA distribution in carcinoma in situ (CIN III) with or without adjacent invasive cancer. In this carefully constructed retrospective study in 20 patients with CIN III, adjacent to invasive cancer, both lesions had an identical DNA pattern, suggesting that the two lesions were related. In 8 patients, all younger than 35 years of age, both lesions were diploid. In 12 patients older than 50, both lesions were polyploid in two cases or aneuploid in 10 cases. Of the 19 CIN III lesions without adjacent invasive cancer 2 were diploid, 7 polyploid, and 10 aneuploid. In personal unpublished studies of precancerous lesions, all CIN I, II, III lesions had at least some cells with hyperdiploid and hypertetraploid DNA values, regardless of the type of HPV present. **The presence of HPV DNA in the nuclei of precursor lesions may have a major impact on these measurements**, as documented by Chacho et al (1990). There is no adequate evidence that **DNA ploidy measurements are of any value as a prognostic factor in precursor lesions and cancer of the uterine cervix.**

Cytogenetic Studies

Integration of HPV DNA in some precursor lesions and in most invasive cancers of the uterine cervix has led to speculations about the impact of these events on the genome of the

P.318

affected cells, and specifically on chromosomal abnormalities (summary in Lazo, 1999). Yet, it has been shown many years ago by conventional cytogenetic techniques that such abnormalities may also occur in precursor lesions wherein HPV DNA is presumably not integrated into the host DNA. Spriggs et al (1962) were the first to demonstrate numerical chromosomal abnormalities and the presence of marker chromosomes in precursor lesions, observations confirmed by Boddington et al (1965), Spriggs et al (1971), Kirkland (1966, 1967), Jones et al (1968), and Granberg (1971). In general, these workers suggested that the level of abnormalities increased with the degree of morphologic abnormalities. Boddington et al (1965) stated that "extensive chromosome rearrangement takes place in precancerous epithelium, often for years before the onset of (invasive) carcinoma." Invasive cervical cancers fell into two groups: those with normal or nearly normal chromosomal component (**diploid range tumors**) and **aneuploid tumors** with increased number of chromosomes; the latter fell into the triploid-tetraploid group and tetraploid group (Wakonig-Vartaaja et al, 1965, 1971; Atkin and Baker, 1982, 1984; Atkin, 1984). It is clear that the tumors in the diploid range are not necessarily free of subtle chromosomal abnormalities that cannot be captured by the techniques used to date. Meisner (1996) used fluorescent in situ hybridization (FISH) technique for chromosomes 11 and X. Cells with an elevated number of signals (3 or higher) were observed more often in HGSIL than in LGSIL.

Recent studies, using the technique of **comparative genomic hybridization (CGH)**, disclosed high levels of genomic instability and one characteristic finding, **a gain in the short arm of chromosome 3** as one of the landmarks of invasive carcinoma of the uterine cervix. This change was observed in tumors with and without documented presence of high-risk HPV DNA (Heselmeyer et al, 1996, 1997). Hidalgo et al (2000) correlated the presence of human papillomavirus type 18 with chromosomal abnormalities in 12 microdissected invasive carcinoma and 12 cell lines. Deletion of the short arm of chromosome 3 and gain in the long arm of the same chromosome were observed in invasive cancer. These findings were at variance with Helsmeyer's work but were confirmed by Guo et al (2001), who reported a **deletion of chromosome 3p** as the most common lesion in cervical cancer. Using the CGH technique on cells isolated from cervicovaginal smears by microdissection, Aubele et al (1998) documented the presence of abnormalities affecting from 6 to 9 different chromosomes in various forms of dysplasia. It remains to be seen whether these data are of practical value. Dellas et al (1999) studied invasive cervical carcinomas stage 1B by CGH. Deletion of the short arm of chromosome 9 (-9p) was associated in a statistically significant fashion with lymph node metastases. Losses of the short arm of chromosome 1 (-11p) and of the long arm of chromosome 18 (-8q) were associated with poor prognosis in the absence of metastases. This study, if confirmed, may prove to be of clinical value.

Some of the more conventional cytogenetic observations were of diagnostic significance: My co-workers, Forni and Miles (1966), **demonstrated large size and increase in number of sex chromatin in abnormal cells exfoliating from precursor lesions**. These findings were confirmed by Naujoks (1969) and Nishiya et al (1981), who correlated the increase in the number of sex chromatin bodies with increased DNA ploidy. Uyeda et al (1966) and Atkin and Brandão (1968) observed, in smears and tissues of precursor lesions, **unusually shaped nuclei with protrusions associated with very long marker chromosomes**. A similar observation was made by Brandão (1987) in koilocytosis.

Clonality Analysis

It is generally assumed that normal tissues are polyclonal (i.e., express paternal and maternal

chromosomes), whereas **cancers** are derived from a single transformed cell and are, therefore, **monoclonal**, expressing only one set of genes. For the uterine cervix, it has been documented, by a variety of approaches, that most LGSIL lesions are polyclonal, whereas HGSIL, invasive cancer are, for the most part, monoclonal (Enomoto et al, 1994; Park et al, 1996; Choi et al, 1997; Guo et al, 1998). El Hamidi et al (2003) microdissected abnormal cells from archival cervicovaginal smears and correlated clonality with behavior. Monoclonal pattern was observed in all CIN III lesions and most CIN II lesions. Some CIN II lesions and all CIN I lesions were polyclonal. All patients with monoclonal pattern (and high-risk HPV) had recurrences despite treatment.

It is obvious, at the time of this writing (2004), that the search for prognostic parameters will continue and may ultimately provide us with reliable tools of clinical value.

CYTOLOGIC PATTERNS AND HISTOLOGIC CORRELATION

Some years after the introduction of cervicovaginal cytology, it became evident that morphologic features of neoplastic cells in smears could be correlated, not only with invasive cancer, but also with precursor lesions of various types, grades, and clinical significance. These observations led to a much better understanding of natural history of carcinoma of the uterine cervix, narrated in Part 1 of this chapter. The differences among cells derived from invasive cancer and from various precursor lesions are sometimes subtle but recognizable and applicable to the practice of cervical cytopathology. As discussed at length in Chapter 7, **cancer cells can be recognized by their marked nuclear abnormalities and classified according to their cytoplasmic features.** The recognition of **precursor lesions** was based on the concept of **dyskaryosis** (from Greek, *dys* = abnormal and *karion* = nucleus) introduced by Papanicolaou (1949). **Dyskaryotic cells differ from cancer cells by their well-differentiated, mature cytoplasm and lesser, although variable, levels of nuclear abnormalities.** Because dyskaryotic cells were often associated with tissue lesions classified as "dysplasia," the term "**dysplastic cells**" is now in current usage in the United States. In the United Kingdom, however, the term "dyskaryosis," classified as to degree of abnormality, is the official form of cytologic diagnosis of cervicovaginal

P.319

samples. In this text, the two terms are synonymous and are used side-by-side.

The cells seen in cervical samples originate from the surface of the epithelial lesion. If the epithelial surface is composed of large, mature, albeit abnormal squamous cells, the cervical sample will contain mainly superficial or intermediate squamous cells with various levels of nuclear abnormalities. Quite often, the abnormal nuclear features of such cells can be better appreciated in the cell samples than in corresponding histologic sections. If the epithelial surface is composed of less mature, smaller cells, this will also be reflected in the cervical sample. Although, in most cervical smears and corresponding liquid preparations, the neoplastic abnormalities are reasonably well characterized and readily recognized, there are many diagnostic pitfalls that are discussed at length in this chapter. The endless variety of abnormal cytologic patterns that may be encountered is sometimes a humbling experience in terms of the observer's ability to deliver at all times a precise and final diagnostic statement on a cytologic sample.

The introduction of liquid methods of cell collection and processing has not rendered the recognition and interpretation of cell abnormalities any easier than the traditional direct smears. Testing for human papillomavirus (see Part 1 and the closing pages of this chapter) has not rendered cervicovaginal cytology obsolete.

Figure 11-30 Karyomegaly and dysplastic/dyskaryotic intermediate and parabasal

squamous cells. *A.* Karyomegaly in intermediate squamous cells with large, somewhat hyperchromatic nuclei. *B.* Karyomegaly in large parabasal cells. *C.* Dysplastic (dyskeratotic) intermediate squamous cells. Note greater nuclear hyperchromasia when compared with *A.* *D.* Dysplastic (dyskeratotic) large parabasal cells. Note irregular nuclear contour.

CLASSIFICATION AND MORPHOLOGIC FEATURES OF NEOPLASTIC CELLS IN CERVICOVAGINAL SMEARS

For didactic purposes, the cell changes in cervicovaginal material may be classified into three categories with **increasing degree of abnormality**:

- **Karyomegaly:** nuclear enlargement in otherwise normal-appearing cells
- **Dysplastic (dyskaryotic) cells:** slight to marked nuclear abnormalities in well-differentiated cells, easily classified as either squamous or glandular
- **Cancer cells:** marked abnormalities of the nucleus and the cytoplasm

This subdivision is artificial inasmuch as these categories of abnormalities frequently overlap and because individual cells may defy this classification.

Nuclear Enlargement, or Karyomegaly, a Component of ASC-US

The term **karyomegaly** (from Greek, *karyon* = nucleus and *megalos* = large) was proposed by Papanicolaou (1949) to describe **enlargement of nuclei occurring in superficial, intermediate, or large parabasal squamous with morphologically normal cytoplasm**, resulting in a somewhat increased

P.320

nucleocytoplasmic ratio. The **cytoplasm** of the affected cells may show **normal folding or cytolysis** during the second half of the menstrual cycle (see Chapter 8). **Karyomegaly occurring in small parabasal squamous cells is usually accompanied by more pronounced nuclear abnormalities.** In the 2001 Bethesda System, **karyomegaly is included in the category of atypical squamous cells of unknown significance or ASC-US.**

Figure 11-31 Koilocytes and pseudokoilocytes. *A.* Large squamous cell with the characteristic features of koilocytes, that is enlarged hyperchromatic nucleus and large, sharply demarcated perinuclear clear zone. *B.* Koilocyte from a liquid preparation (ThinPrep). *C.* A cluster of smaller koilocytes from another liquid preparation (SurePath). *D.* Squamous cells with cytoplasmic clearing but without nuclear abnormalities or sharply demarcated halos. These cells should not be mistaken for koilocytes.

Karyomegaly and similar abnormalities of **endocervical cells** are classified in the 2001 Bethesda System as “**atypia of glandular cells of unknown significance**” (previous **AGUS**), are discussed further on in this chapter and in Chapter 12. I have never been persuaded that karyomegaly may be observed in endometrial cells (see Chapter 13).

In karyomegaly of squamous cells, the enlarged nuclei are of normal, spherical shape with smooth nuclear membranes. The nuclei may be transparent, but are more often opaque or somewhat hyperchromatic (Fig. 11-30A,B). Karyomegaly with significant nuclear hyperchromasia blends with cell changes observed in dysplastic (dyskaryotic) cells (see below).

Karyomegaly represents an abnormality of the nuclear structure. It has been proposed that karyomegaly represents the **earliest, but reversible, nuclear change** in human papillomavirus (HPV) infection (Stoler 2003). The presence of HPV in the nuclei of karyomegalic cells may be documented by in situ hybridization.

Kurman and Solomon (1994) suggested that **nuclei enlarged “two and a half to three times”** above the size of normal nuclei of intermediate squamous cells may qualify as karyomegaly or ASC-US. This definition should not be taken as an absolute requirement because, in routine work, the sizes of the nuclei are not measured. Still, only **conspicuous nuclear enlargement** may qualify as karyomegaly. The **increase** in nuclear sizes is **best verified by comparing the nuclear size of an atypical cell with the nuclear size of adjacent normal cells. The term karyomegaly should be limited by the number of such cells in the preparation.** In our experience, a preparation containing more than 6 to 8 karyomegalic superficial or intermediate squamous cells **should be classified as low-grade squamous intraepithelial neoplasia (LGSIL).** The diagnosis of a neoplastic lesion is easier if karyomegaly is observed **in the company of other abnormal cells**, notably dysplastic (dyskaryotic) cells, particularly koilocytes (see below).

Karyomegaly must be differentiated from slight **nuclear enlargement occurring in inflammatory and regenerative processes**, described in Chapter 10. If slight nuclear enlargement **affects a large proportion of squamous cells in a smear, it is unlikely to be neoplastic and may be caused by technical problems in smear preparation or fixation, early menopause, or effects of therapy, such as radiotherapy.**

P.321

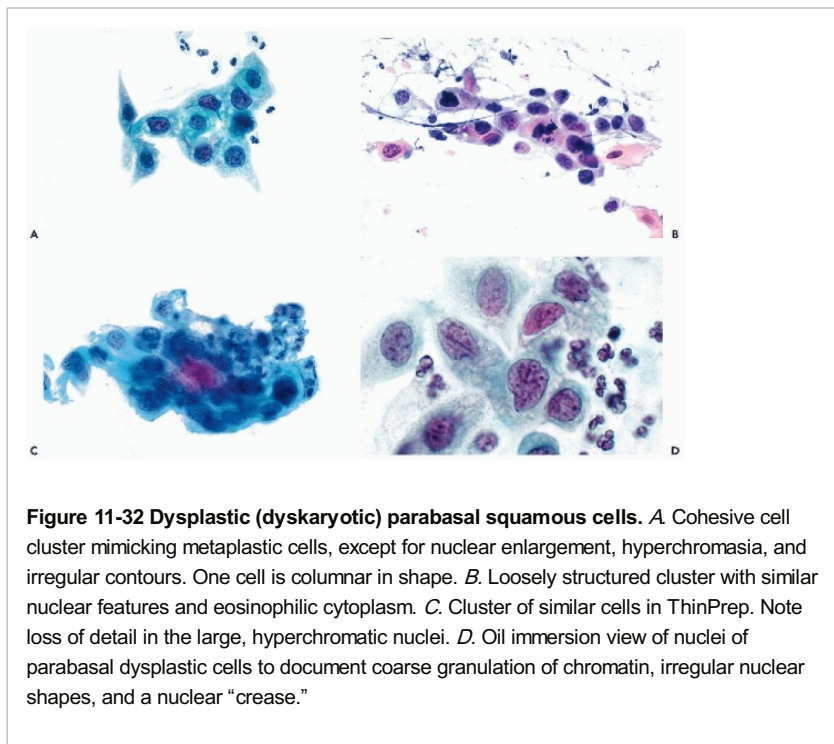

Figure 11-32 Dysplastic (dyskaryotic) parabasal squamous cells. *A.* Cohesive cell cluster mimicking metaplastic cells, except for nuclear enlargement, hyperchromasia, and irregular contours. One cell is columnar in shape. *B.* Loosely structured cluster with similar nuclear features and eosinophilic cytoplasm. *C.* Cluster of similar cells in ThinPrep. Note loss of detail in the large, hyperchromatic nuclei. *D.* Oil immersion view of nuclei of parabasal dysplastic cells to document coarse granulation of chromatin, irregular nuclear shapes, and a nuclear “crease.”

Diagnostic Significance of Karyomegaly

In the past, the term **atypia** was often used to describe karyomegaly limited to a few cells. This term has been replaced in the 2001 Bethesda System by **ASC-US**. The outcome of ASC-US or karyomegaly is variable. In most cases, the abnormality is transient and will not be found in subsequent smears. Personal experience suggests, however, that **patients with “atypia” or karyomegaly are at an increased risk for future neoplastic events** (see also discussion of atypical smears later in this chapter). In some cases, colposcopy and biopsy will disclose a low-grade squamous intraepithelial lesion (LGSIL) but sometimes even a high-grade squamous neoplastic lesion (HGSIL) or, in rare cases, **invasive cancer**, as will be documented below.

Testing for human papillomavirus to triage patients with ASC-US is described in the closing pages of this chapter. Briefly, the test has a **high negative predictive value**. Patients testing negative for the virus are not likely to develop neoplastic lesions but the fate of patients testing positive is much less secure.

Dysplastic (Dyskaryotic) Cells

Regardless of size, such cells, observed mainly in **precursor lesions of squamous**

carcinoma of the uterine cervix, are characterized by enlargement and other nuclear abnormalities, occurring in otherwise well differentiated squamous and endocervical cells (Figs. 11-30C,D, 11-31, 11-32, 11-33, 11-34, 11-35 and 11-36).

The nuclear enlargement within cells with a relatively normal cytoplasm results in an increased nucleocytoplasmic (N/C) ratio; this change is more readily observed in larger, rather than smaller cells. In some cells, the nuclear enlargement is identical to that observed in karyomegaly (see Fig. 11-30C,D).

Other nuclear abnormalities pertain to nuclear staining, texture, and configuration. The intensity of nuclear staining may vary from relatively slight hyperchromasia to markedly hyperchromatic nuclei. The nuclei may be dark and homogenous (see Fig. 11-32A,B) or show an abnormal chromatin texture in the form of coarse clumping of chromatin, commonly associated with a thickening of the nuclear membrane and nuclear creases or folds (see Fig. 11-32D). The nuclei also display an irregular contour in the form of small indentations, notches or spikes, visible under the high power of the microscope (see Fig. 11-30D). Irregularly shaped nuclei with finger-like projections (presumably caused by long marker chromosomes) may occur (Atkin and Brandão, 1968). Nuclear break-up or apoptosis is common (Fig. 11-33A).

P.322

Enlarged and multiple, sometimes irregular, nucleoli may be observed, usually in cells of endocervical rather than squamous origin (see Fig. 11-34D). Multinucleated dysplastic (dyskaryotic) cells occur from time to time (Fig. 11-36C). The nuclei in such cells are usually hyperchromatic but relatively small.

Figure 11-33 Parabasal dysplastic (dyskaryotic) squamous cells. A Loosely structured cluster of parabasal cells with abnormal nuclei. The cytoplasm is either basophilic or eosinophilic, the latter suggestive of squamous lineage. In the center, a cell with apoptotic nucleus (*arrow*). B A cluster of similar cells in SurePath. C, D. Thick clusters of abnormal parabasal cells in a direct smear (C) and in a ThinPrep (D). The nuclear detail is sharper in C. Such clusters are sometimes referred to as “syncytia,” an inaccurate term (see text).

The presence of two or more inactivated X chromosomes (**sex chromatin or Barr bodies**), in the form of approximately triangular dense fragments of chromatin attached to the nuclear membrane, may be occasionally noted under the high power of the microscope (see Fig. 11-36D). This finding is of diagnostic value as it **indicates an abnormal chromosomal component and is therefore almost unequivocal evidence** of a neoplastic change (Forni and Miles, 1966; Nishiya et al, 1981). Barr bodies are difficult to identify in cells with coarsely clumped chromatin. For further discussion of Barr bodies, see Chapters 4, 8, 9, and 29.

In some dysplastic (dyskaryotic) cells, the nuclei show the characteristic abnormalities of nuclear contour and the presence of nucleoli, but **hyperchromasia may be absent** (see Fig. 11-34D). The term **pale dyskaryosis** describing this phenomenon is found in the British literature (summaries in Smith and Turnbull, 1997; Coleman and Evans, 1999).

Nature of Nuclear Abnormalities

The nuclear abnormalities in dysplastic (dyskaryotic) cells are similar to those occurring in cancer cells, though less pronounced. The possible **role of E6 and E7 human papillomavirus genes in generating such changes** was discussed in Part 1 of the chapter

and was recently summarized by Stoler (2003). It is, therefore, interesting to note that **similar nuclear abnormalities occur in precancerous lesions and cancer of organs other than the uterine cervix, where the role of the virus remains enigmatic or unproved.** Further, similar changes can be observed in cervical smears and tissues of mice treated with **methylcholanthrene**, a known carcinogenic agent (von Haam and Scarpelli, 1955). The mitotic inhibitor, **podophyllin**, applied to the human cervix prior to hysterectomy, results in somewhat similar abnormalities (Saphir et al, 1959; Kaminetzky and McGrew, 1961). As early as 1958, I observed cytologic abnormalities, similar to dyskaryosis, in patients treated with

P.323

cytotoxic chemotherapeutic agents (for further discussion of this topic, see Chapter 18).

Figure 11-34 Cells from a small-cell carcinoma in situ (CIN III). A. An overview of a smear showing multiple clusters of small cancer cells, which may be readily overlooked on screening. B, C. Examples of tiny cancer cells, some showing coarse chromatin pattern and cytoplasmic vacuolization. D. A cluster of small cancer cells with pale nuclei and visible nucleoli (so-called pale dyskaryosis).

These data strongly suggest that dyskaryosis represents a major upheaval of the nuclear chromatin and DNA, which is either transient, perhaps because the affected cells die out, or may be the precursor of important neoplastic lesions that, in some cases, may lead to invasive cancer. Much additional research will be required to explain the nature and the unpredictable behavior of these cell abnormalities.

Classification

The squamous dysplastic cells may be classified as superficial, intermediate (usually combined in the same category), parabasal, and small parabasal or basal. This classification has diagnostic significance. The most common and important variant of intermediate dysplastic squamous cells is **koilocytosis**.

Koilocytes

As defined by Koss and Durfee in 1956, **koilocytes are mature squamous cells, usually of the intermediate type, characterized by abnormal, enlarged and hyperchromatic, single, double or, rarely, multiple nuclei surrounded by large, sharply demarcated perinuclear clear zones or halos. The nuclei are usually smudged and homogeneous** (see Fig. 11-31A,B). The clear zones are sharply demarcated at their periphery and are surrounded by a residual rim of the cytoplasm. **Koilocytes may be larger than normal superficial squamous cells and may occur singly or in clusters**, the latter particularly well seen in some types of liquid preparations (see Fig. 11-31C). **The presence of nuclear abnormalities, regardless how slight, is essential for the recognition of koilocytes.**

The koilocytes are **pathognomonic of a permissive human papillomavirus (HPV) infection**. In the nuclei of such cells, mature virions can be documented by electron microscopy (see Fig. 11-6), by reaction with broad-spectrum antibody to viral capsular proteins (see Fig. 11-9), and by in situ hybridization with DNA probes to viral DNA (see Fig. 11-10). Koilocytosis is **not HPV-type dependent**, as it may be caused by any type of HPV virus, whether "low-" or "high-" risk (see Part 1 of the chapter). Other minor cell changes, sometimes attributed to HPV infection, such as **pseudoparakeratosis** or **karyorrhexis**, are not reliable as evidence of viral presence (Tanaka et al, 1993).

Koilocytes are dead cells, victims of HPV infection. The perinuclear "cavity" represents a zone

of cytoplasmic necrosis, which is demarcated at the periphery by an accumulation of residual cytoplasmic fibrils (see Fig. 11-6). Recher (1984), using scanning electron microscopy, confirmed that

P.324

the “halo” portion of koilocytes was depressed, indicating a collapse of the cytoplasmic filaments.

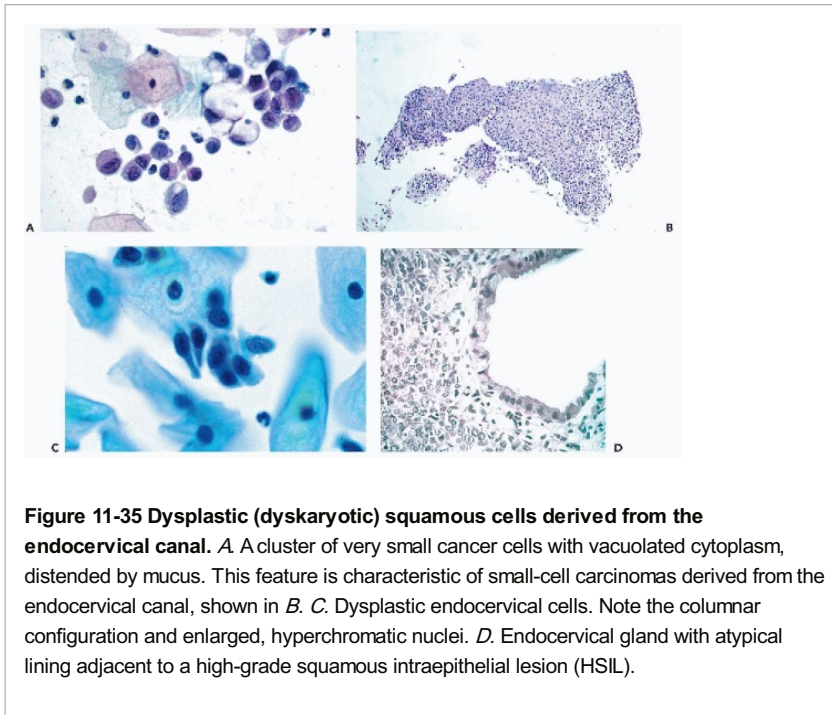

Figure 11-35 Dysplastic (dyskaryotic) squamous cells derived from the endocervical canal. *A.* A cluster of very small cancer cells with vacuolated cytoplasm, distended by mucus. This feature is characteristic of small-cell carcinomas derived from the endocervical canal, shown in *B.* *C.* Dysplastic endocervical cells. Note the columnar configuration and enlarged, hyperchromatic nuclei. *D.* Endocervical gland with atypical lining adjacent to a high-grade squamous intraepithelial lesion (HSIL).

The **nature of the nuclear abnormalities** in koilocytes has not been conclusively settled. Lucia et al (1984) and Chacho et al (1990) reported that, in contrast to normal squamous cells, some of the nuclear DNA in koilocytes is not digestible by deoxyribonuclease (DNase, type I). In fact, Lucia et al suggested that this nuclear feature is, per se, diagnostic of HPV infection, as previously suggested by Williams (1961). These observations suggest that the **nuclear abnormalities in koilocytes may, in part, be caused by the presence of viral DNA, and in part, by repackaging of cellular DNA caused by viral infection.** Thus, **measuring the DNA content in koilocytes** and other cells infected with HPV, either by image analysis using Feulgen stain or by flow cytometry, **is most likely inaccurate.** It is unknown why some of the koilocytes are larger than normal squamous cells of similar type.

Koilocytes **must be differentiated from inflammatory cell changes**, such as seen in infection with *Trichomonas vaginalis* and occasionally other organisms, which may cause **slight nuclear abnormalities and narrow perinuclear clear zones** (see Fig. 10-16). Occasionally, intermediate squamous cells, **without obvious nuclear abnormalities, may display large perinuclear clear zones**, similar to those seen in koilocytosis, but not as sharply demarcated at their periphery (see Fig. 11-31D). Such cells may be difficult to classify and are sometimes considered as “atypias of squamous cells of unknown significance” (ASC-US). In my experience, such cytoplasmic “atypias” have limited clinical significance and usually disappear spontaneously. **An artifact mimicking koilocytes** has been reported in ThinPrep preparations from women receiving **oral contraceptives** (Morrison et al, 2000). These authors attributed the change to pressure induced alteration of glycogen.

Diagnostic Significance. Koilocytes are seen predominantly in low-grade squamous intraepithelial lesions (LGSIL) with features of HPV infection. However, such cells **may also be observed in some high-grade squamous lesions (HGSILs) and even in invasive squamous cancers**, as documented below.

Superficial and Intermediate Dysplastic (Dyskaryotic) Squamous Cells

These cells originate in the squamous epithelium of the cervix and vagina. They **differ from koilocytes by the absence of the perinuclear “cavitation”** but share with them

P.325

their size which is equal to, or occasionally larger than, their normal counterparts (see Fig. 11-30C). The **homogeneous cytoplasm is usually thin and transparent but may be opaque, eosinophilic, or basophilic.** In some women of childbearing age, the cytoplasm of the intermediate cells may follow cyclic changes. **The nuclei are, by definition, enlarged and**

may show variable degrees of abnormality, ranging from hyperchromasia to more complex abnormalities described above.

Figure 11-36 Trapping of cancer cells in streaks of endocervical mucus. *A, B.* Smear containing numerous cancer cells obtained by a scraper. Note the sheets of malignant cells. *C.* Multinucleated dysplastic (dyskaryotic) cells. Note the large size of hyperchromatic nuclei. *D.* Triple sex chromatin bodies (Barr bodies) in a high-grade cervical intraepithelial neoplasia shown under high magnification (*arrows*).

Parabasal Dysplastic (Dyskaryotic) Cells

These **smaller squamous cells** may be derived either from the surface of lesions of squamous epithelium or from lesions mimicking squamous metaplasia, located in the endocervical canal. The cells vary in diameter from 20 to 12 μm in size and may closely resemble **normal parabasal or metaplastic squamous cells** by their configuration and the staining qualities of their relatively scanty, **basophilic or eosinophilic cytoplasm** (see Fig. 11-32). Although the basophilic cytoplasm of such cells may appear to be perfectly normal, some abnormalities of configuration, in the form of **irregular cell contour** or **molding of the cytoplasm** of adjacent cells, may be observed (see Fig. 11-32A). The cells with eosinophilic cytoplasm resemble small squamous cancer cells (see Fig. 11-32B).

The enlarged, usually hyperchromatic nuclei of these cells show the classical marked abnormalities of nuclear size, shape, and configuration, as described above. It warrants repeating that in some cells of this type, **the chromatin may be pale and the recognition is based mainly on abnormalities of chromatin configuration, nuclear shape, and the presence of nucleoli (pale dyskaryosis)** (see Fig. 11-34D).

The parabasal dyskaryotic cells, particularly of smaller sizes, may appear **singly or in sheets and tight clusters** (see Figs. 11-32 and 11-33). In direct cervical smears, such cells may be trapped in the endocervical mucus and form **strings or files** that are extremely characteristic (see Fig. 11-36A,B). **This relationship is lost in specimens collected in liquid media. In tight clusters**, sometimes referred to as “**syncytia**,” the identity of the cells may be difficult to recognize (see Fig. 11-33C,D). The term **syncytia** is catchy but faulty, because these cells do not merge and have retained their identity. At the periphery of such clusters, the classical nuclear abnormalities may be recognized. Usually the tight clusters are accompanied by detached single dysplastic cells, which are much easier to recognize.

P.326

Small Parabasal and Basal Dysplastic Cells (Small Cancer Cells)

As a rule, these cells originate from the abnormal epithelium of the endocervical canal and **virtually always reflect the presence of an important and potentially dangerous neoplastic lesion**. The classification of these cells as either “**dysplastic cells**” or as “**small cancer cells**” is semantic and a matter of personal preference. **These diagnostically very important small cells**, about 10 to 15 μm in diameter, have clearly abnormal nuclei and very **scanty cytoplasm that is usually basophilic**, and may **form vacuoles** (see Figs. 11-34B,D, 11-35A). The cells occur **singly or form small, loosely structured clusters. Tightly knit clusters or “syncytia” may sometimes occur** (see Fig. 11-34C). The full appreciation of the **nuclear abnormalities** requires high magnification that will disclose abnormal nuclear contour and coarse granulation of the chromatin (see Fig. 11-32D).

The recognition and classification of these small cancer cells is one of the great challenges of

cervical cytology, as they are one of the **main sources of false-negative diagnostic errors**. **The single small cells may be overlooked on screening; the clusters may be mistaken for inflammatory cells, endometrial cells, or a host of other small cells** (see Fig. 11-34A). Close attention to nuclear abnormalities is necessary to prevent errors.

Dysplastic (Dyskaryotic) Endocervical Cells

These cells originate in the epithelium of endocervical type. They are relatively **uncommon and often difficult to recognize**, particularly in thick cell clusters obtained with endocervical brushes (see Chapter 10). By definition, these are **columnar endocervical cells with enlarged nuclei that are either hyperchromatic or relatively pale**, and often contain **large nucleoli** (see Fig. 11-35C). It is a matter of semantics whether the small cancer cells with mucincontaining cytoplasmic vacuoles should also be classified as endocervical (see Fig. 11-35A), although they always originate in lesions of the endocervical canal. **Dysplastic endocervical cells** may be observed in high-grade squamous epithelial lesions (see Fig. 11-35B) or in adjacent benign, but atypical, endocervical glands (see Fig. 11-35D). This accounts for the high rate of squamous neoplastic lesions observed in smears with atypias of glandular cells (formerly AGUS; see discussion below). Similar abnormalities may also occur in the **early stages of endocervical adenocarcinoma**, discussed in Chapter 12. Occasionally, **endometrial cells may mimic endocervical cells and vice versa**, as discussed at length in Chapter 13. The diagnostic reproducibility in the morphologic recognition of these abnormalities of glandular cells is low (Simsir et al, 2003).

Benign abnormalities of endocervical cells occurring in **inflammation, pregnancy, hormone-induced changes or “repair,”** may mimic endocervical cell dyskaryosis. These benign abnormalities were discussed in Chapter 10 and will be brought up again in Chapter 12.

Diagnostic Significance of Dysplastic (Dyskaryotic) Cells

Depending on the size and type of these cells, they reflect **various types of precursor lesions and sometimes invasive cancer of the cervix**. **The correlation of cell patterns with types of lesions is discussed below.**

CANCER CELLS

Cancer cells, whether derived from invasive cancer or high-grade precursor lesions, usually display significant **nuclear and cytoplasmic abnormalities**. Still, many of the cancer cells are **differentiated**, that is they retain a clear-cut tissue identity with cytoplasmic features, corresponding to either squamous or glandular epithelium. If the origin of cancer cells is not evident, the cells should be classified as **undifferentiated cancer cells**.

This **classification of cancer cells is arbitrary** and its purpose didactic. Transitional cell forms exist between dysplastic and differentiated cancer cells and between differentiated and undifferentiated cancer cells. For this reason, it is often impossible to classify accurately a single cell, nor would such a procedure be essential or desirable. As will be pointed out repeatedly, **most cytologic diagnoses are established on *patterns* of abnormal cells, rather than on single cells**.

Differentiated Cancer Cells

Cancer Cells of Squamous Origin

Squamous cancer cells are characterized by an extraordinary **variety of cell shapes** and formation of **abundant keratin**. These cells have a **characteristic bright orange, or occasionally yellow, cytoplasm that is thick and dense and lacks the transparent qualities of normal squamous or superficial dyskaryotic (dysplastic) cells** (Fig. 11-37A). This cytoplasm does not follow the cyclic changes that are sometimes observed in dyskaryotic cells. The **size of keratinized cancer cells** varies from very large, comparable with or larger than normal superficial squamous cells, to as small as small parabasal cells. Their shape varies from round or polyhedral to spindly, to irregular and bizarre. The **nuclei** of such cells are usually **hyperchromatic, coarsely granular, and of irregular shape** and frequently undergo pyknosis, giving them a dense, “**drop of India ink**” appearance. The **nuclear sizes are variable** and may vary from conspicuous enlargement to nearly normal. In some of these cells, the **nuclei may become pale** and, in final stages of keratinization, may **disappear** altogether, submerged by overgrowth of keratin. Such **anucleated squames of bizarre shapes** (see Fig. 11-37B) are diagnostically as important as the nucleated squamous cancer cells, but must be differentiated from benign squames, found in innocuous leukoplakia (see Chapter 10).

“**Tadpole**” cells (**cells with a tail or caudate cells**) are fairly uncommon cells observed mainly in **invasive squamous cancer of the cervix** and, occasionally, also in **high-grade squamous precursor lesions**. They are elongated, club-shaped cells of variable sizes, with

one broad and one narrow end. The usually spherical, or somewhat irregular, hyperchromatic **single or multiple nuclei** are eccentrically

P.327

located within the broad area of the cytoplasm (see Fig. 11-37C). The degree of cytoplasmic keratinization is variable.

Figure 11-37 Keratinizing squamous cancer cells. *A.* Malignant squamous cells of variable sizes with large hyperchromatic nuclei. *B.* Keratinized nucleated and anucleated cells. *C.* A so-called tadpole cell with large nucleus forming the head and long, thin cytoplasmic tail. *D.* Squamous pearl wherein the component cells have large hyperchromatic nuclei.

Spindly squamoid cells occur most often in invasive epidermoid cancers of the cervix but may also be observed in keratinized high-grade precursor lesions. These cells are elongated and **needle-shaped** and vary in length from 10 to 40 μm (see Fig. 11-51C). Keratinization is not always evident and, thus, the cytoplasm may be either eosinophilic or basophilic. Elongated filaments (**Herzheimer's fibrils**) may be sometimes observed within the cytoplasm of spindly cells (Potter, 1978). The nuclei are nearly always elongated, hyperchromatic, and large for the size of the cell. **Nuclear abnormalities must be observed before such cells are classified as malignant, because benign spindly squamous cells, smooth muscle cells and fibroblasts, may occasionally occur in cervical smears.** The spindly squamoid cells may be the only cancer cells in cervical smears that will allow the correct cytologic classification of a poorly differentiated carcinoma as squamous or epidermoid type.

Squamous "pearls" are **concentrically arranged clusters of squamous cancer cells** that resemble similar clusters of benign squamous cells described in Chapter 10. The difference between the benign and malignant "pearls" is in the configuration of the **nuclei**, which, in the cancerous pearl, are **enlarged and hyperchromatic** (Fig. 11-37D). In the **center** of the cancerous pearl, one may occasionally observe a **deposit of keratin** that stains orange or yellow in Papanicolaou stain. The pearls are usually observed in invasive squamous cancers but, occasionally, may be encountered in high-grade squamous precursor lesions.

Cancer Cells of Endocervical Glandular Origin

The differences between dysplastic and cancerous endocervical cells are trivial (compare Fig. 11-35 with Fig. 11-38). These cells are usually of **columnar configuration** and their basophilic cytoplasm is either homogeneous or contains one large or several smaller **cytoplasmic vacuoles**, wherein **mucin** may be demonstrated by special stains (see Fig. 11-38). As mentioned above, mucus vacuole formation may also occur in small squamous dysplastic or cancer cells of endocervical origin (see Figs. 11-34C and 11-35A). In such cells, the **nuclei are large** and are often **eccentric**. In larger cancer cells, **nuclear hyperchromasia** and coarsely filamentous chromatin are less frequent than in squamous cancer cells, but **large, eosinophilic nucleoli** are often present. **Nuclear pyknosis**, so characteristic of keratinized cells of squamous origin, **is generally absent**. **Papillary, spherical cell clusters** may occur in adenocarcinomas of the cervix (see Chap. 12).

Other glandular cancer cells in cervicovaginal material

P.328

may be derived from endometrial, ovarian, or metastatic carcinomas and are described in Chapters 13, 16, and 17.

Figure 11-38 Glandular cancer cells. A,B. Columnar cancer cells with vacuolated cytoplasm and enlarged hyperchromatic nuclei with visible nucleoli, derived from the endocervical epithelium.

Diagnostic Significance of Differentiated Cancer Cells

Although by definition, the cancer cells should reflect the presence of an invasive carcinoma, this is not always the case. Such cells **may also occur in precursor lesions, particularly of squamous type**. It is also important to emphasize that **glandular cancer cells may be shed from squamous or epidermoid cancers of the cervix involving the endocervical canal** (see Fig. 11-35A,B) and are, therefore, **important evidence of anatomic location of the lesion**. Such cells may also be derived from **atypical, but noncancerous, endocervical glands adjacent to high-grade lesions** (see Fig. 11-35C,D). This point will be brought up again in discussing the cytologic presentation of the various forms of cervical cancer.

Undifferentiated Cancer Cells

These cells are, in a way, the embodiment of cancer and represent, in a classic fashion, the **cytoplasmic and nuclear characteristics of malignant cells**. For all practical purposes, they are always derived from invasive cancer. Their **cytoplasm**, although varying in amount, is **generally scanty**, predominantly **basophilic**, and fails to display any features that would enable one to classify the cells according to the tissue of origin (Fig. 11-39A,B). The cells may **vary in size from very small ones, about 10 μ m in diameter or even less**, to occasional **gigantic multinucleated forms** (see Fig. 11-41C). Their shape varies considerably, but most of the cells are approximately spherical or oval. The **nuclei** display all the changes attributable to cancer cells, such as a relatively **large size, hyperchromasia, irregular contour, coarsely filamentous chromatin, prominent nucleoli, and frequently mitotic activity** (Fig. 11-39D). However, **large, pale, homogeneous nuclei** occur from time to time in cancer cells in **invasive squamous cancer**. There is nearly always a marked reversal of the nucleocytoplasmic ratio in favor of the nucleus. Cytoplasmic fragility and degeneration result in cell **debris** or in isolated “**naked**” nuclei. Nuclear necrosis and karyorrhexis (apoptosis) are common.

Undifferentiated cancer cells may form **large clusters, wherein the classical features of cancer cells are absent because of poor preservation of the cells**. A careful examination of such clusters under high power of the microscope will often disclose the presence of **large nucleoli within the poorly preserved, often pale, large nuclei**. In such cases, it is highly advisable to **search for single cancer cells with more classical features**. Undifferentiated cancer cells are usually accompanied by debris, fresh and lysed or fibrinated blood, and leukocytes—all constituting evidence of necrosis and inflammation accompanying advancing or advanced cancer, and sometimes referred to as “**cancer diathesis**.”

IMPACT OF COLLECTION OF CERVICAL SAMPLES IN LIQUID MEDIA ON MORPHOLOGY OF CELLS

The basis of a correct cytologic diagnosis of neoplastic abnormalities of the epithelium of the uterine cervix is the assessment of the relationship of various types of abnormal cells to each other. **At all times, the pattern of abnormalities is more significant than abnormalities of individual cells** and a careful **synthesis of the cytologic evidence** is required before a diagnosis can be rendered. Unfortunately, with the use of **liquid media** for collection of cell samples and automated processing, the **pattern of lesions, seen in direct smears, particularly the entrapment of abnormal cells in the endocervical mucus** (see Fig. 11-36A,B), is **lost and the diagnosis must be based on assessment of individual cells or cell clusters**. This disadvantage is compensated by **reduction or absence of obscuring blood and inflammatory debris**. In our experience with the SurePath (TriPathology Imaging, Inc., Burlington, NC), the **quality of the preparations, the distribution and dispersion of cells, and the morphologic details of normal and abnormal cells are outstanding and**

comparable to routine smears (see Figs. 11-31C and 11-35C). In the ThinPrep

P.329

System (Cytyc Corporation, Boxborough, MA), the cell distribution is sometimes uneven, there is some shrinkage of cells, and the crispness of the nuclear structure is not as sharp as in routine smears (see Figs. 11-32C and 11-33D). The ThinPrep System requires considerable training and experience in the interpretation of these preparations.

Figure 11-39 Undifferentiated cancer cells. *A.* A thick cluster of cancer cells derived from an invasive cancer. *B.* Dispersed stripped nuclei of cancer cells of variable sizes. *C.* A very large single cancer cell. *D.* High magnification showing an abnormal mitotic figure in a malignant cell.

Incidentally, one of the much touted advantages of liquid preparations, namely the spread of cells as a monolayer, is not correct. Often, thick clusters of cells obtained by brushing (including endocervical, endometrial, dysplastic, or cancer cells), are not dispersed and are in a different plane of vision than the single cells forming the background (see Figs. 11-31C, 11-32C, and 11-33D). The results reported with the liquid systems are discussed in the closing pages of this chapter.

CORRELATION OF CYTOLOGIC AND HISTOLOGIC PATTERNS OF SQUAMOUS PRECURSOR LESIONS OF THE UTERINE CERVIX

One of the important features of cervicovaginal cytology is that the **type of abnormal cells and the degree of cell and nuclear abnormalities may be reasonably correlated with the type of lesion present in the uterine cervix.** As discussed in the opening pages of this chapter, the smears reflect the degree of maturation of the epithelium of origin. Thus, the presence of large, superficial dysplastic (dyskaryotic) squamous cells, particularly koilocytes, suggests a lesion with a mature surface, which, in most cases, is a low-grade squamous intraepithelial lesion (LGSIL). The presence of smaller dysplastic (dyskaryotic) squamous (or sometimes glandular) cells will reflect a lesion with a surface composed of immature smaller cells and, hence, a high-grade lesion (HGSIL), often located within the endocervical canal. Although cells showing the highest degree of nuclear and cytoplasmic abnormality and classified as cancer cells are observed mainly in invasive cancer, they may also occur in high-grade precursor lesions. The border between smaller dysplastic (dyskaryotic) cells and cancer cells is often blurred and the designation of these cells in either category depends on the preference of the observer.

The relationship of various cell types and the corresponding histologic lesions is illustrated in a diagram, in which the proportions of dysplastic (dyskaryotic) cells of various types and cancer cells in a cervical sample are plotted against the degree of tissue abnormality (Fig. 11-40).

Borrowing

P.330

an expression from the field of hematology, the increase in the less mature dysplastic (dyskaryotic) cells and cancer cells represents a “shift to the left,” corresponding to the increasing degree of abnormality in histologic preparations. This is also illustrated in a series of diagrams representing the distribution patterns of various types of abnormal cells in the lesions of the epithelium of the cervix. There is an increase in small cells and in the nucleocytoplasmic ratio in high-grade squamous intraepithelial lesions, carcinoma in situ (HGSIL), and invasive cancer when compared with the patterns of a low-grade lesion (Fig. 11-41). Supporting

evidence for this concept was provided by Reagan et al (1952,

P.331

1957) who, using **planimetry**, calculated the **nuclear and cellular diameters** of abnormal cells in low-grade lesions (dysplasia), high-grade lesions (represented by carcinomas in situ), and invasive carcinomas of the uterine cervix. A **gradual decrease in cell size with a synchronous increase in the nucleocytoplasmic ratio and the occurrence of aberrant cell types were recorded with increasing severity of the tissue lesions** (Tables 11-8 and 11-9). Figure 11-42 illustrates the distribution of abnormal cell types in squamous precursor lesions of the uterine cervix according to the epithelium of origin.

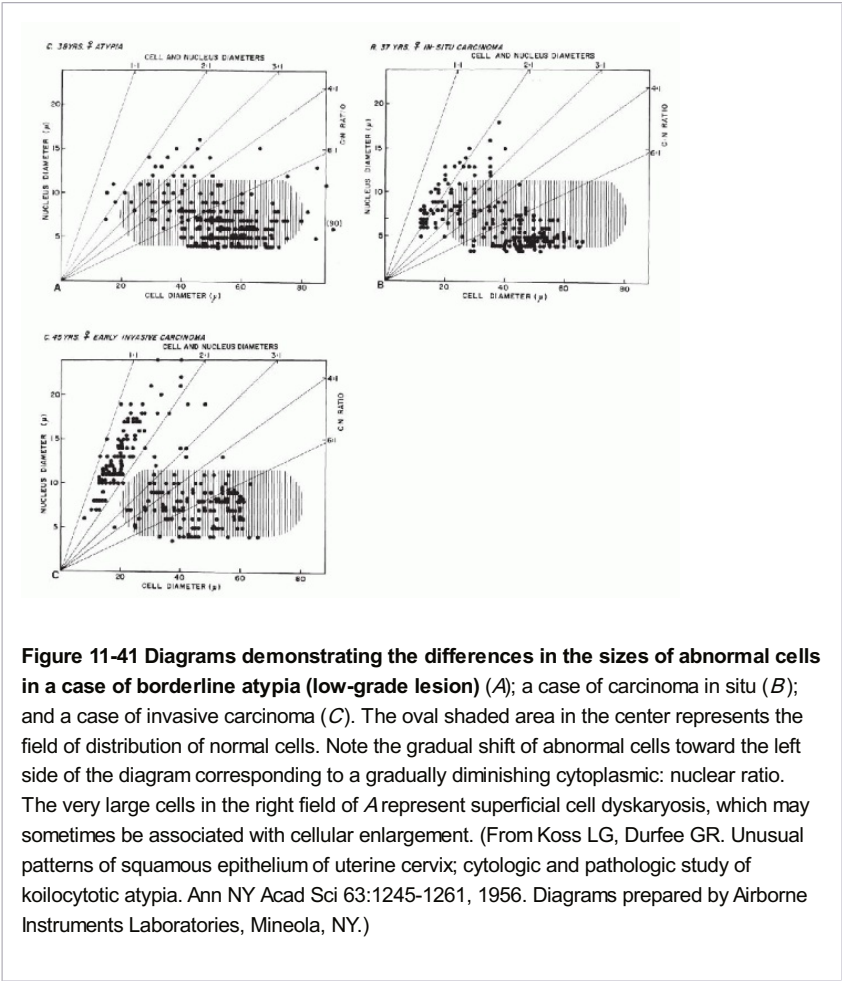

TABLE 11-8 MEASUREMENTS OF CELL AREA

	Normal	Dysplasia	In Situ Cancer	Invasive Cancer
Cases	50	100	100	100
Total cells measured	2,500	5,000	10,000	5,000
Cell				
Diameter in μm	44.93 \pm 4.28	36.81 \pm 5.59	20.85 \pm 3.16	16.85 \pm 2.94
Area in μm^2	1,604.15 \pm 312.35	1,087.59 \pm 311.00	352.51 \pm 115.78	229.49 \pm 82.81
Nucleus				
Diameter in μm	6.75 \pm 1.20	14.52 \pm 1.57	11.67 \pm 1.652	9.78 \pm 1.59
Area in μm^2	36.51 \pm 13.31	167.20 \pm 38.20	109.38 \pm 33.04	77.04 \pm 26.57
Relative nuclear area*	2.32% \pm 84	16.45% \pm 4.35	31.96% \pm 6.040	34.44% \pm 6.77

* All areas represent means/case and were computed on the basis of measured dimensions except for invasive cancer, which is based on planimetry. See legend to Table 11-9.

Johannisson et al (1966) **documented that the number and type of abnormal cells in a cervical scrape smear could be correlated with size and type of lesion**, confirming a common experience of cytopathologists, namely that a well-taken smear showing a small number of abnormal cells, usually corresponds to a small lesion, whereas a smear with a large number of abnormal cells usually indicates a lesion of large size. The cytologic recognition of various types of precancerous intraepithelial lesions is discussed below.

TABLE 11-9 CELL CONFIGURATION*				
	Normal (%)	Dysplasia (%)	In Situ Cancer (%)	Invasive Cancer (%)
Number of cells	11,000	5,000	10,000	10,000
Type of cell				
Polyhedral	94.81	52.68	8.19	2.05
Round	.95	20.58	52.63	45.98
Oval	2.81	21.02	31.41	30.53
Ellipsoidal	1.21	4.00	1.67	.54
Irregular	.21	.20	4.08	5.17
Elongate	.01	1.50	1.76	15.08

Tadpole	.00	.02	.26	.65
Isodiametric	95.76	73.26	60.82	48.03
Nonisodiametric	4.24	26.74	39.18	51.97

* Tables 11-8 and 11-9 indicate the variation of cell characteristics in normal cervix, dysplasia (synonymous with low-grade lesions as used in the present work), and in situ and invasive carcinoma of the cervix. Note the increase in the relative nuclear area and the increase in irregular cell shapes as the lesions progress to invasive carcinoma.

(Reagan JW, Hamonic MJ, and Wentz WB. Analytical study of the cells in cervical squamous-cell cancer. Lab Invest 6:241-250, 1957.)

It must be stressed that, quite often, the correlation of the cytologic and histologic patterns of lesions is far from perfect. Knowledge of such pitfalls is important as it may prevent errors of interpretation.

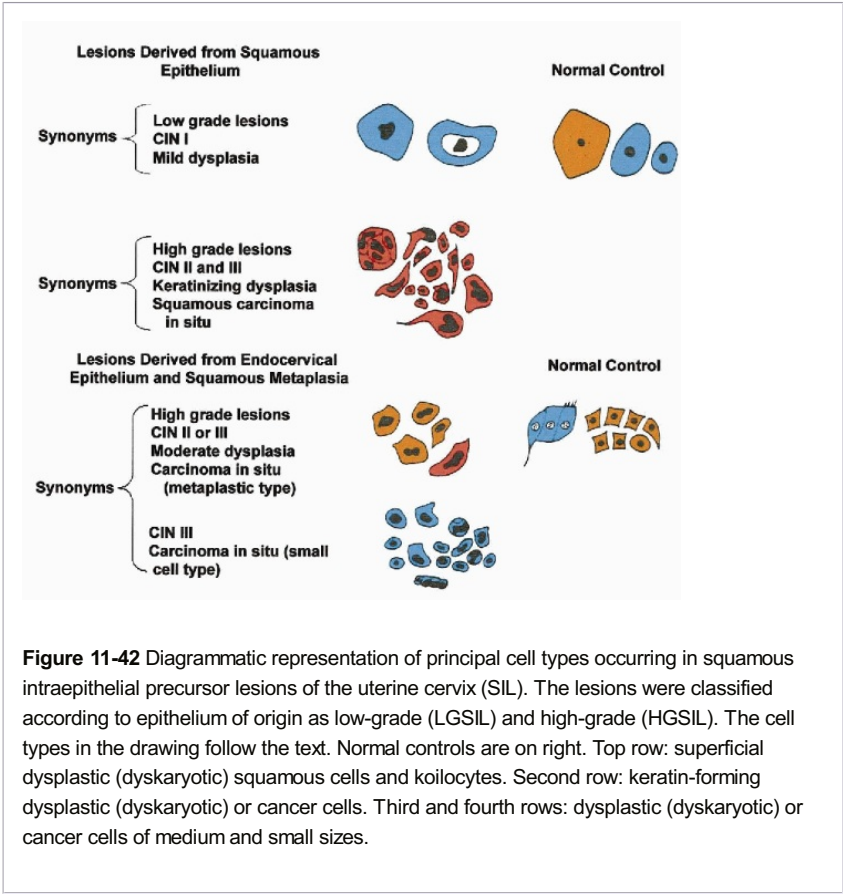

Protruding Papillary Squamous Lesions of the Cervix

Condylomata Acuminata ("Condylomas")

The natural history of *condylomata acuminata*, or venereal warts, occurring on external genitalia, was discussed in Part 1 of the chapter in conjunction with the role of human papillomavirus (HPV) in the genesis of these lesions. **Large condylomas**, visible with the naked eye and similar to those observed on the external genitalia, are **uncommon on the**

P.332

uterine cervix and rarely require a cytologic diagnosis. Still, occasionally, cytologic samples are obtained. **The cytologic presentation of these lesions differs from the more common, flat lesions.** I have observed several such cases in young women.

Histology

The lesions in their classic form are composed of a central stalk of connective tissue lined by thick squamous epithelium arranged in numerous papillary folds (Fig. 11-43A). Toward the

surface, the epithelium is characterized by the presence of koilocytes, in the form of cells with enlarged single or double hyperchromatic nuclei, surrounded by a clear perinuclear zone (Fig. 11-43B). Mitotic activity may be intense. A few layers of small, keratinized cells are commonly seen on the surface of these lesions. The **presence of HPV** may be documented in the nuclei of koilocytes by the use of the common HPV capsular antigen (see Fig. 11-9A) or by in situ hybridization with specific HPV type DNA (see Fig. 11-9B). In the perirectal condylomas studied by us, the dominant HPV types were **6 or 11** but, occasionally, **types 16 or 18** have been observed (Vallejos et al, 1987).

The studies of patterns of distribution of glucose-6-phosphate dehydrogenase suggest multicellular origin of these lesions, contrary to monocellular (clonal) origin of cervix cancer (Friedman and Fialkow, 1976). Jagella and Stegner (1974) studied **DNA distribution** in 50 condylomas and found aneuploid DNA values in several such lesions. Other observers claimed that the DNA content of condylomas is "polyploid." In our own studies, virtually all such lesions had an abnormal, aneuploid DNA pattern (Vallejos et al, 1987).

Cytology

The **cytologic presentation** of large cervical condylomata in direct smears may be alarming. Besides cells showing moderate levels of nuclear atypia, the lesions may shed **large, highly abnormal squamous cells**, showing **marked nuclear enlargement and hyperchromasia** (Fig. 11-43C,D). Occasionally, concentric arrangement of squamous cells or "**squamous pearls**" may be noted. Sheets of **small, spindly squamous cells with hyperchromatic nuclei**, derived from the surface of the lesions, may also occur. Classical **koilocytes**, with large hyperchromatic, sometimes smudged, single or double nuclei, are usually present but **rarely constitute the majority population in the wart-like lesions**.

Clinical Significance

The clinical significance of the protruding, wart-like lesions of the cervix **is somewhat obscure. At least some of these lesions may recur after treatment and may be accompanied or followed by flat precursor lesions (CIN) or even invasive cancer, justifying their inclusion among precancerous lesions.** The **practical conclusions** based on these considerations suggest that the cytologic abnormalities caused by *condylomata acuminata* must receive the same clinical attention as other precancerous lesions of the uterine cervix. Prudence suggests that these patients should have the benefit of a colposcopic examination of the cervix and of the vagina. **All persisting lesions are deserving of biopsy and further treatment must depend on the histologic findings.**

Solitary Squamous Papilloma

It is not known whether **the rare solitary squamous papillomas of the cervix**, occurring mainly in patients below

P.333

the age of 40, are related to *condylomata acuminata* or constitute a distinct and different lesion. Histologically, solitary squamous papillomas of the cervix are structurally similar to a *condylomata acuminata*, but the surface squamous epithelium shows only slight deviation from normal (Kazol and Long, 1958). Koilocytes are absent. Because of the rarity of these lesions, their relationship to HPV is unknown. However, unless widely excised, these lesions have a tendency to recur, and at least some of them are ultimately capable of invasive growth. A case of this type was reported by Marsh (1952). Goforth (1952) reported two such cases with adjacent carcinoma in situ. I have also observed a few such cases, **followed many years later by invasive squamous cancer.** Squamous papillomas should not be confused with **papillary (warty) and verrucous squamous carcinomas of the cervix**, discussed below, and similar lesions of the vagina, discussed in Chapter 14.

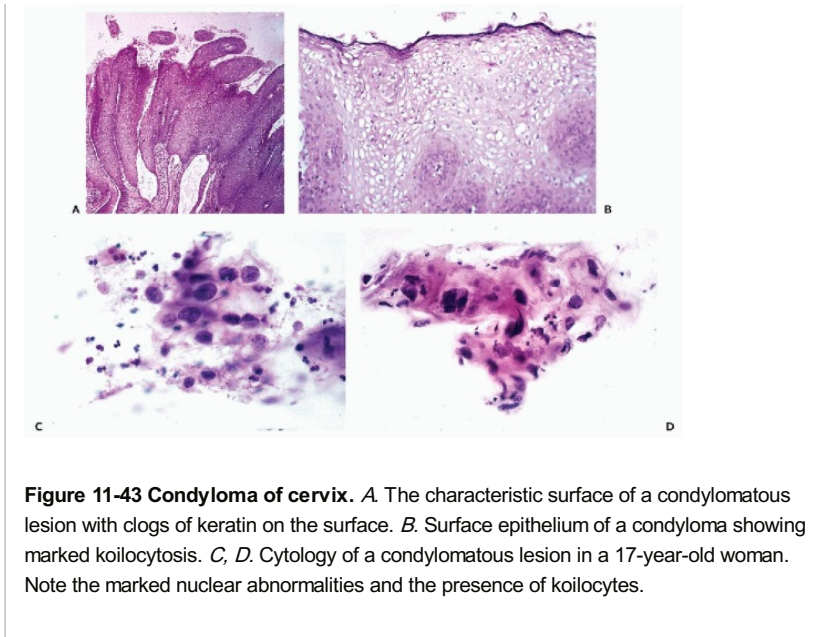

Figure 11-43 Condyloma of cervix. *A.* The characteristic surface of a condylomatous lesion with clogs of keratin on the surface. *B.* Surface epithelium of a condyloma showing marked koilocytosis. *C, D.* Cytology of a condylomatous lesion in a 17-year-old woman. Note the marked nuclear abnormalities and the presence of koilocytes.

FLAT PRECURSOR LESIONS

Low-Grade Squamous Intraepithelial Lesions (LGSILs)

Synonyms: mild dysplasia, cervical intraepithelial neoplasia (CIN), grade I (with or without features of human papillomavirus infection), “flat condylomas.”

Histology

As briefly discussed in Part 1 of the chapter, the low-grade precancerous lesions of the uterine cervix occur **mainly on the squamous epithelium of the transformation zone and in the adjacent squamous epithelium of the outer (vaginal) aspect of the uterine cervix.** These lesions are characterized by a relatively slight disturbance of the structure and maturation of the squamous epithelium. The squamous epithelium can be of **normal thickness** (Fig. 11-44B) or **thickened**, the latter feature being most conspicuous in the so-called “flat condyloma” variant of the lesion (see Fig. 11-45B,D). **These lesions may extend to adjacent endocervical glands in the transformation zone and to the epithelium of the vagina.** **Nuclear abnormalities in the form of nuclear enlargement and hyperchromasia** may be scattered throughout all layers of the epithelium, but are often **most conspicuous in the upper one-third**, particularly in the presence of koilocytes. The **surface** of many of these lesions shows a few layers of **small keratinized cells, so-called “dyskeratocytes”** (Meisels, 1984). **Mitotic activity** is commonly present in the lower one-third, occasionally extending to the middle, very rarely to upper layers of the epithelium. Abnormal mitoses may occur. As has been discussed above, **all types of HPV** may be associated with these lesions (see Table 11-4). Hence, HPV typing as an

P.334

adjunct to cytology that has been proposed as an “objective” system of classification of these lesions (Sherman et al, 1994) should be applied with caution, if at all, in this group of patients, particularly if they are less than 30 years of age. For further discussion of HPV typing as an adjunct to cytology, see Part 1 of the chapter and further comments below.

The **most common error** in the histologic diagnosis of these lesions is **normal squamous epithelium rich in glycogen**, wherein normal intermediate and superficial squamous cells may show large clear cytoplasm, **mistaken for koilocytes. Such epithelia do not show nuclear abnormalities, an essential feature of low-grade lesions.** Pirog et al (2002) proposed that positive immunostaining for a marker for cell proliferation (**MIB antibody**) is helpful in separating the normal from abnormal epithelia.

Cytology

The **background of the smears** is often clear and free of inflammation. Corresponding to the histologic picture, the **dominant abnormal cells in the cervical smears, derived from the relatively mature surface of the epithelial lesion, belong to the category of superficial and intermediate dysplastic (dyskaryotic) cells** (Figs. 11-44A,C and 11-45C). **Koilocytes, singly and in clusters**, occur in a great many of these cases, confirming the close relationship of the low-grade lesions with permissive HPV infection (Fig. 11-45A,B). Some observers proposed that, in the presence of koilocytes, it is possible to establish a diagnosis of **human**

papillomavirus infection, suggestive of viral presence in the absence of histologic abnormalities. As shown by Abadi et al (1998), this is not the case and the cytologic or histologic diagnosis of "human papillomavirus infection" is not helpful.

Figure 11-44 Low-grade squamous intraepithelial lesions (LGSILs). *A.* Large intermediate dyskaryotic cells corresponding to biopsy shown in *B.* *B.* In situ hybridization of the biopsy with HPV 16. Note the dark nuclei showing evidence of HPV in the upper regions of the epithelium. *C.* A multinucleated dyskaryotic cell corresponding to low-grade CIN shown in *D.* Similar multinucleated cells may be observed in the epithelium.

Also commonly observed in such smears are **clusters or dense aggregates of small, usually spindly squamous cells with markedly eosinophilic cytoplasm and small, pyknotic nuclei, "so-called" dyskeratocytes** (Fig. 11-46A,C), derived from the surface of the epithelium (Fig. 11-46B,C). **Sheets of such cells** may be observed in liquid preparations from LGSIL.

In samples from some low-grade lesions, the **superficial and intermediate dysplastic (dyskaryotic) cells and koilocytes** are accompanied by **smaller, parabasal dysplastic (dyskaryotic) squamous cells** (see Fig. 11-32A,B). The classification of the material as to low- or high-grade squamous lesions depends on the **proportion of the smaller cells**. If only a few smaller dysplastic (dyskaryotic) cells are present, the lesion should still be judged to be low-grade. If the **population of the smaller dyskaryotic cells is 10% or more of the abnormal cells, it becomes likely that the**

P.335

low-grade lesion is accompanied by a high-grade lesion in the adjacent epithelium. In some liquid preparations, the two populations of cells can be better visualized than in conventional smears.

Figure 11-45 Low-grade squamous intraepithelial lesions with koilocytes. *A.* Numerous koilocytes in one field of a cervical smear corresponding to the tissue biopsy shown in *B.* *B.* A low-grade intraepithelial lesion with koilocytes. *C.* A cluster of large dysplastic intermediate squamous cells corresponding to the tissue biopsy shown in *D.* *D.* A low-grade lesion that extended into the endocervical glands.

While koilocytes characteristically occur in low-grade lesions, they may also be found in smears of keratinized carcinoma in situ (keratinizing dysplasia) and, occasionally, in invasive squamous cancer. Thus, Allerdin (1985) observed koilocytes in 25% of earlier smears of patients with biopsy-documented carcinoma in situ. Further, koilocytes derived from a low-grade lesion may obscure the presence of high-grade lesions (HGSIL) located in an adjacent epithelial segment. These views received strong support in an analysis of koilocytotic atypia by Lee et al (1997). In some patients, koilocytosis may precede a high-grade lesion, or even invasive cancer, by several years (Fig. 11-47).

Superficial dysplastic cells may also occur in or precede high-grade lesions. In the example shown in Figure 11-48A,B, superficial dysplastic (dyskaryotic) cells corresponded to a **two-tier neoplastic lesion**, with the bottom part of the epithelium formed by a high-grade lesion. In the case illustrated in Figure 11-48C,D, scanty superficial cell dysplasia (dyskaryosis) corresponded to a high-grade lesion in the biopsy.

Clinical Significance

As has been repeatedly emphasized in Part 1 of the chapter and above, the behavior of the low-grade lesions is unpredictable. Many of these lesions **disappear** spontaneously or after a biopsy (Fig. 11-49) but may also persist or progress. There is evidence that some **LGSILs are extremely fragile and, therefore, susceptible to minimal therapeutic handling, perhaps even to cytologic sampling**. However, **neither cytologic nor the histologic patterns of abnormality permit prognostication in any individual case; hence, the patients must have long-term follow-up, as they are prime candidates for further abnormalities**.

Kurman et al (1994) recommended that patients with LGSIL should either have the benefit of a colposcopic examination or close cytologic surveillance. If the latter is chosen, experience has shown that at least 3 years of completely negative cytologic follow-up is necessary before the patient may be declared to be free of disease (Koss et al, 1963).

HPV typing, discussed in the closing pages of this chapter, is, at the time of this writing (2004), the most widely used prognostic test, which, unfortunately, is not reliable in women below the age of 30 in whom LGSIL is most often observed. Still, Matsuura et al (1998) claimed that disappearance vs. persistence and progression of LGSIL correlated

P.336

with the presence or absence of HPV. Molecular and genetic approaches so far failed to establish a reliable and simple set of parameters applicable to routine cytologic or histologic samples. In an elaborate recent study, Kruse et al (2004) reported that lesions with a high level of expression of proliferation antigen Ki67 were more likely to progress than lesions with low values.

Figure 11-46 Low-grade squamous intraepithelial lesions with dyskeratocytes. *A*. Cluster of keratinizing superficial cells, commonly observed in, but not diagnostic of, low-grade lesion shown in *B*. *B* shows a low-grade squamous intraepithelial lesion with koilocytes. Note the keratinized cells on the surface. *C*. A small cluster of densely packed, small squamous cells described by Meisels as "dyskeratocytes." *D*. A low-grade lesion with koilocytes showing surface keratinization corresponding to *C*.

High-Grade Squamous Intraepithelial Lesions (HGSILs)

Synonyms: moderate dysplasia, marked (severe) dysplasia, carcinoma in situ, cervical intraepithelial neoplasia (CIN) grades II, III, “atypical condylomas.”

High-grade squamous intraepithelial lesions show **a variety of histologic and cytologic patterns that may cause diagnostic controversy, even among competent observers.**

One of the benefits of the Bethesda System was the introduction of a **binary system of classification** of the precancerous lesions of the cervix (low- and high-grade), replacing three or even four subdivisions that were not reproducible.

The easiest to define is a lesion with severe abnormalities throughout the epithelial thickness, known as **carcinoma in situ**. This writer has searched in vain for an objective and reproducible definition of the term **moderate dysplasia**, or CIN II, which some observers include with low-grade and some with high-grade lesions. It is obviously a subjective diagnosis that may depend, to a large extent, on the training and experience of the pathologist. A number of lesions with moderate nuclear changes and some surface differentiation of the neoplastic epithelium, some illustrated in this chapter, could be so classified. For example, low-grade lesions shown in Figures 11-44D and 11-45D could be reclassified as CIN II or moderate dysplasia. Keratin-forming high-grade lesions (see Fig. 11-47D) could also be classified as CIN II, so could the lesions shown in Figures 11-48D and 11-52D. The significance of this lesion is illustrated in Figure 11-56, showing its transition into invasive cancer. Hence, the precise cytologic or histologic definition of the lesion is of limited value, **so long as the lesion is recognized** and included in the group of precancerous lesions, requiring further investigation and treatment. Regardless of morphology, nearly all lesions belonging to the HGSIL group harbor persisting infection with a high risk human papillomavirus (see Table 11-2).

There are very few cases of a high-grade lesion that have an identical histologic or cytologic presentation. However, **the population of abnormal cells in individual cases is**

P.337

often remarkably uniform. Marked variability of cell configuration is more consistent with invasive cancer.

Figure 11-47 Dysplastic (dyskaryotic) intermediate squamous cells with halos (koilocytes), corresponding to a high-grade lesion observed 4 years later. *A.* Dyskaryosis of intermediate cells. *B.* Small cancer cells observed on a smear obtained 4 years later. *C.* Tissue biopsy obtained after the second smear shows carcinoma in situ (CIN III) with extension to endocervical glands. *D.* Shows details of the surface of the lesion.

For didactic purposes, the high-grade lesions may be divided into three principal morphologic groups, illustrated in Figure 11-16:

- **Keratin-forming lesions** derived from and retaining the characteristics of squamous epithelium
- **Lesions derived from endocervical epithelium**, often retaining features of squamous metaplasia
- **Lesions derived from reserve cells**, usually of endocervical origin, characterized by small cancer cells, sometimes with endocrine features

These subtypes of high-grade lesions are not necessarily homogeneous and oftentimes **several patterns may be observed side by side within the same cervix.** However, this **classification is reproducible, to a significant extent, in cervical smears and it does**

provide guidance to the location of the lesion, either on the uterine portio or in the endocervical canal.

High-Grade Keratinizing Squamous Intraepithelial Lesions

Synonyms: keratin-forming carcinoma in situ, keratinizing or pleomorphic dysplasia, moderate dysplasia, severe dysplasia, CIN grade II or III.

As may be seen from the number of synonyms, this is a group of lesions that presents considerable difficulties in diagnosis and classification. The lesions are **located primarily on the squamous epithelium of the portio of the cervix and occasionally have a keratinized surface and, hence, may clinically resemble benign leukoplakia**. These lesions are sometimes “warty” and may resemble squamous papilloma. An association of these lesions with condylomas was reported by McLachlin et al (1995). Transitions between low- and high-grade keratinizing lesions may also be observed (Fig. 11-50B).

Most high-grade lesions of this type represent a **transformation of low-grade squamous intraepithelial lesions** and are precursor lesions of well differentiated, keratinized invasive cancer of the cervix or vagina. It cannot be ruled out, however, that some of these lesions may develop de novo in squamous epithelium. Although, to my knowledge, no statistical evaluation of the frequency of these lesions has been performed, it has been my experience that these lesions have become much less common in the United States in recent years, possibly as a consequence of detection and treatment of low-grade lesions. The keratinizing precursor lesions of the uterine cervix and the corresponding well-differentiated invasive squamous cancer are still common in countries without an effective cancer-detection program.

P.338

Figure 11-48 Low-grade lesions in smears with high-grade squamous lesions (HGSIL) in tissue biopsies. *A*. Dysplastic (dyskaryotic) intermediate squamous cells corresponding to biopsies shown in *B*. *B* shows a two-layer lesion with the high-grade component forming the bottom segment. *C*. An intermediate dyskaryotic cell in Pap smear corresponding to a HGSIL in the tissue biopsy shown in *D*.

Histology

These lesions are nearly always derived from, and located on, the squamous epithelium of the vaginal aspect of the uterine cervix. The epithelium is usually thickened **and is composed of squamous cancer cells with markedly enlarged, usually hyperchromatic nuclei, arranged in disorderly layers. Mitoses, often abnormal, can be observed throughout the cancerous epithelium. Layers of keratin of variable thickness are present on the surface of the lesions which still retain the over-all configuration of the squamous epithelium of origin** (Figs. 11-50D, 11-51D). These lesions may **extend to the lower end of the**

P.339

endocervical canal but more often spread to the vagina (see Chap. 14).

Figure 11-49 Disappearing low-grade lesion in a 17-year-old woman. *A*. Severe dyskaryosis of intermediate cells corresponding to the tissue biopsy of a low-grade lesion shown in *B*. The lesion disappeared after the biopsy and long-term follow-up was negative.

Figure 11-50 High-grade squamous intraepithelial lesion. *A*. Group of keratinized squamous cancer cells showing large, dark nuclei, corresponding to biopsy shown in *B*. Note the presence of cells with clear perinuclear zones reminiscent of koilocytes. *B*. The lesion is a combination of low and high-grade with keratinized surface. *C*. Anucleated squamous material corresponding to tissue lesions shown in *D* that shows squamous high-grade CIN with keratinized surface.

In biopsy material, the lesions are frequently underestimated because, under the low power of the microscope, they may be mistaken for **benign leukoplakia**, or, because of the relatively orderly arrangement of the epithelium, considered to be a “**dysplasia**” or a **low-grade lesion**. Such material should be studied under a **high-power lens** to identify the **cytologic abnormalities** described above. The lesions are fully capable of progression to **invasive cancer**.

Cytology

The **smear background** shows considerable inflammation. Associated **trichomoniasis** is **common**. The presence of blood and marked necrosis may be indicative of invasive cancer. The dominant feature is usually the presence of **keratin-forming cancer cells of a variety of shapes with abundant orange or yellow opaque, thick cytoplasm**, accounting for the term “**pleomorphic dysplasia**” (Patten 1972) (Figs. 11-50 and 11-51). **Tadpole (caudate) cells** (see Fig. 11-37C), **spindly squamous cancer cells** (see Fig. 11-51C), and **squamous “pearls”** made up of cancer cells (see Fig. 11-37D) may be observed in such smears. The **nuclei of such cells, although enlarged and of irregular shape, are often pyknotic and not amenable to a detailed microscopic analysis (India ink nuclei)** (see Fig. 11-50A). Some of the cancer cells may sometimes appear as mere “**ghosts**,” in which the nucleus has been partially or completely replaced by keratin. **Anucleated keratin material from the surface of the lesion** may accompany the ghost cells (see Fig. 11-50C). In fact, the **differential diagnosis between benign leukoplakia, which also sheds anucleated squames** (see Chap. 10), and **keratinizing cancer of the cervix, is best accomplished by a cytologic sample**. The samples may also contain **nonkeratinized, dysplastic cells and koilocytes**, the latter suggestive of origin of the abnormality in a low-grade lesion (see Fig. 11-50A).

In some of these lesions, the cytologic evidence may be limited to a few atypical

squamous cells. It must also be noted that, in this group of lesions, **the cytologic differentiation of noninvasive precursors from invasive, keratin-forming squamous cancer may be impossible**, as recently confirmed by Levine et al (2003).

Clinical Significance

Because of the **possibility that an invasive cancer may be present**, an adequate **colposcopic evaluation and biopsies**

P.340

of cervix are particularly important for this group of lesions and must include the adjacent vagina.

Figure 11-51 Various manifestations of a keratinizing high-grade squamous intraepithelial lesion. *A.* A cluster of small squamous cells with dark, enlarged nuclei. *B.* Single squamous cells with large, hyperchromatic nuclei. *C.* Spindly squamous cells. *D.* Corresponding biopsy of a high-grade lesion with keratinized surface. Note the presence of tripolar mitoses.

Intraepithelial Lesions with Features of Squamous Metaplasia

Synonyms: moderately well-differentiated or intermediate type of carcinoma in situ, large- or medium-size cell carcinoma in situ, moderate or severe dysplasia, CIN grade II or III.

Histology

This is, by far, the most common form of high-grade lesion, **usually straddling the transformation zone, and involving the adjacent squamous and endocervical epithelia.** **The extension of the process into endocervical glands is common and should not be mistaken for invasive cancer.** The cytologic and histologic appearance of the lesions is variable, which accounts for the many synonyms.

The neoplastic epithelium is of **variable thickness**, usually comprising 10 to 20 layers of cells, but it sometimes may be composed of only three or four layers of small cells. In such cases, the lesion may be difficult to recognize and one must pay close attention to the nuclear features of component cells. The very thin epithelium may reflect **loss of upper epithelial layers** because of fragility of these lesions. These cases are reminiscent of the “**clinging**” form of **carcinoma in situ of the bladder**, discussed in Chapter 23. The over-all histologic pattern and anatomic distribution of the epithelial lesions often bears considerable resemblance to squamous metaplasia of the endocervical epithelium. The neoplastic epithelium is **composed of medium-sized cancer cells arranged in disorderly layers.** On close inspection, the cells have **large, irregularly shaped, hyperchromatic nuclei and scanty basophilic cytoplasm** (see Figs. 11-52C, 11-53B,D, 11-54D). **In some lesions, the component cells retain squamous features, are somewhat larger, and have eosinophilic cytoplasm.** Some of these lesions show **two or three layers of small, keratinized cells with pyknotic nuclei** on the surface (see Fig. 11-52D). **Mitotic activity, including abnormal mitotic figures, is usually quite evident. These lesions are often accompanied by atypia of endocervical epithelium lining the adjacent glands** (see Fig. 11-35D).

Some of these lesions are composed of two layers of malignant cells of different morphology (see Fig. 11-48B). The mechanisms of this arrangement are not understood but it is likely that one type of lesion is growing underneath and undermining the older abnormal

surface epithelium.

P.341

Figure 11-52 High-grade squamous intraepithelial lesion of the “so-called” metaplastic type. *A,B.* Parbasal malignant squamous cells with marked nuclear enlargement and hyperchromasia. Note the general similarity of these cells to benign metaplasia, except for marked nuclear abnormalities. *C.* The tissue lesion corresponding to smear pattern shown in *A* and *B*. *D.* Another biopsy example of this type of lesion with keratin formation on the surface.

Differential Diagnosis Between HGSIL of Metaplastic Type with Atypical or Immature Squamous Metaplasia

Atypical or immature metaplasia is an ill-defined histologic entity that is either benign, neoplastic *ab initio*, or may be a step in the development of high-grade lesions of metaplastic type. One such lesion, named **papillary immature metaplasia (PIM)** and often containing HPV types 6 and 11, was thought to represent an early stage of formation of condyloma (Crum et al, 1996).

The lack of diagnostic reproducibility among competent observers was vividly illustrated in a paper by Park et al (1999). These authors attempted to use human papillomavirus typing to solve the problems of classification with limited success. On the other hand, Geng et al (1999) reported **progression of 13 of 16 patients with “atypical immature metaplasia” to HGSIL**. The progression was more frequent in HPV-positive than in HPV-negative patients. Such lesions have been observed by us during the long-term follow-up of cervical neoplasia, reported in Part 1 of the chapter and in recent years.

The histologic differential diagnosis between atypical metaplasia and HGSIL may be very difficult. The **principles in the histologic classification of these lesions can be summarized as follows: if, on close inspection, the epithelium shows formation of desmosomes (intracellular bridges) and the component cells show no conspicuous nuclear abnormalities, the odds are that the lesion is benign. If the cells show variation in nuclear sizes, crowd each other and do not form visible desmosomes, the lesion is most likely malignant.** Some such lesions may become invasive (see Fig. 11-56A,B). The **cytologic material may provide an answer in difficult cases:** in the presence of cells with malignant nuclear features, the lesions are malignant. If the cytology shows merely metaplastic cells with relatively slight nuclear abnormalities, as described in Chapter 10, the identity of the lesions is uncertain and a follow-up should be instituted.

Cytology

In general, this group of lesions is characterized by a fairly monotonous population of **moderately sized parbasal, dysplastic (dyskaryotic) or cancer cells with marked nuclear abnormalities**, occurring singly and in clusters (see Figs. 11-52A,B and 11-54). **Not all such cells have hyperchromatic nuclei (pale dyskaryosis)** and their identification may be challenging. The cytoplasm of the abnormal cells is predominantly basophilic. However, in every sample,

P.342

some or most cells show the eosinophilic cytoplasm, characteristics of squamous cancer cells that may not be evident in the corresponding biopsy (see Fig. 11-53A,B). In some instances, **cancer cells of endocervical type with large nucleoli** may be observed, sometimes

mimicking to perfection the cytologic presentation of endocervical adenocarcinoma (see Fig. 11-53C,D).

Figure 11-53 The smear pattern and histology of a high-grade squamous intraepithelial lesion located in the endocervical canal. *A,B.* An example of HGSIL with keratinization of component cells. *A.* Medium-sized cancer cells with keratinized cytoplasm. *B.* The corresponding tissue lesion. *C.* Columnar cancer cells that could be interpreted as endocervical adenocarcinoma. *D.* The corresponding tissue lesion.

As illustrated in Figure 11-36A,B, **streaks of dysplastic cells**, trapped in endocervical mucus, may be observed in **direct cervical smears**. This diagnostically very helpful feature is no longer present in liquid cell collection systems. Still, in our experience, with good liquid preparations using the SurePath System (TriPathology Imaging, Burlington, NC), the abnormal cells stand out because of nuclear enlargement and hyperchromasia and retain the fine features of nuclear chromatin (Fig. 11-54).

Because the parabasal dysplastic (dyskaryotic) cells may bear considerable resemblance to benign metaplastic squamous cells, some observers have redescribed these cells as “**atypical immature squamous metaplastic cells**” (Dressel and Wilbur, 1992; Sheils and Wilbur, 1997), while acknowledging that such cells reflect the presence of high-grade lesions in most cases. Sherman et al (1999) used this term to designate smears as “atypical, rule out high-grade lesions.” In my judgment, **this term is highly misleading** and merely confuses the issues. In some patients, the **atypical metaplastic cells in smears may be followed by clear-cut dysplastic or malignant cells**, leading to a biopsy diagnosis of HGSIL (Fig. 11-55).

Clinical Significance

It is generally assumed that HGSIL of the metaplastic type is a precursor of invasive cancer, composed of medium-sized cells. **It is of note that invasive carcinomas derived from such lesions may show a much greater degree of keratin formation than the precursor lesions.** By consensus, HGSIL should be treated after the lesion has been localized by colposcopy and appropriate biopsies, although it is known that some such lesions can disappear or not progress for many years (see Part 1 of the chapter). The issue of HPV typing as a prognostic parameter will be discussed at the end of this chapter.

High-Grade Lesions Composed of Small Cells

Synonyms: small-cell squamous (epidermoid) carcinoma, carcinoma in situ, CIN grade III.

P.343

Figure 11-54 High-grade squamous intraepithelial lesion (HGSIL) from a liquid preparation (SurePath). *A,B.* Scattered small malignant cells, singly and in clusters. Note the excellent quality of nuclear stain. *C.* High power view of large cells with hyperchromatic nuclei. Note the irregular nuclear outline and coarse arrangement of chromatin. *D.* Corresponding HGSIL of “metaplastic” type.

Histology

This group of intraepithelial lesions, derived from reserve or basal cells of the endocervical epithelium, is **composed of small malignant cells. The lesions replace the epithelium lining the endocervical canal and frequently extend to endocervical glands** (Figs. 11-57D, 11-58D). The lesion may extend to the transformation zone and be identified by colposcopy. In many instances, however, **the lesion is beyond the reach of the colposcope** and, therefore, represents a diagnostic challenge to the clinician and the pathologist. Because the initial colposcopy may be negative, **delays in securing biopsies are common.**

Endocervical curettage, which is often used for diagnosis, may result in tiny fragments of tumor that are sometimes difficult to interpret or are overlooked. In many cases, **repeated biopsies or diagnostic conization may be required** to secure the diagnosis, a procedure that is sometimes reluctantly undertaken by the gynecologist, and only if the follow-up smears remain positive and the pathologist insists on further diagnostic procedure. Not uncommonly, the lesion is accompanied by **abnormalities of endocervical epithelium and glands that have the features of adenocarcinoma in situ** (see Fig. 11-53C and Chapter 12). The small-cell lesion is the **precursor of invasive cancer composed of small- or medium-sized cells that may have endocrine features.** Because of the problems with cytologic detection of these lesions, they are often discovered in invasive stage and are thought to have rapid progression (see below).

Cytology

This group of lesions, corresponding to the “classic” carcinoma in situ, is characterized primarily by **very small cancer cells with scanty, often barely visible, usually basophilic, rarely eosinophilic cytoplasm**, occurring singly and in clusters (Figs. 11-57, 11-58 and 11-59). The single, dispersed cancer cells **have relatively large, hyperchromatic, coarsely granular nuclei that usually show irregularity of contour. Cells with “pale” nuclei may also occur (“pale dyskaryosis”)** (see Fig. 11-35C). In some cases, **large nucleoli** may be observed, but this is not a common finding. Because the cells are very small (10 to 15 μm in diameter), an examination under the **high power of the microscope** is often needed for the recognition of the nuclear abnormalities (see Figs. 11-57C, 11-58C). The small cancer cells may show **mucus-containing cytoplasmic vacuoles, confirming their kinship with endocervical epithelium** (see Fig. 11-35A).

Equally important for the diagnosis is the presence of **tightly knit cell clusters, sometimes incorrectly referred to as “syncytia”** (see Figs. 11-57B,C, 11-58A, and 11-59B). The number of clusters depends on the technique of cytologic sampling; in smears obtained by cervix scraper, the clusters may be few but, with the use of an endocervical brushing instrument, clusters are usually numerous. The recognition of the nature of the clusters may also require the use of the **high power** of the microscope. If the centers of the clusters are too dense for analysis, the **periphery will virtually always disclose the characteristic nuclear features of the small cancer cells.**

Figure 11-55 Atypical metaplastic cells preceding HGSIL. *A.* Metaplastic cells with nuclear abnormalities. *B.* Cells with similar characteristics forming a cluster. *C.* Small cancer cells observed one year later. *D.* Biopsy obtained after second smear, showing a HGSIL.

P.345

Figure 11-57 HGSIL composed of small cells. *A,B.* Clusters ("syncytia") of very small cancer cells easily overlooked on screening. *C.* High-power view of the cluster shown in *B* to document coarse chromatin pattern and the presence of nucleoli. *D.* Tissue lesion corresponding to *A-C*, showing a small-cell HGSIL that extended into endocervical glands.

It must be stressed that this type of high-grade lesion is, **by far, the most difficult cervix lesion to identify in cytologic preparations**, if the observer is unaware of the small size and microscopic characteristics of cancer cells. Errors occur when such cells are **mistaken for leukocytes, plasma cells, small macrophages (histiocytes), small clusters of benign**

metaplastic or endometrial cells. The last error may occur in brush specimens, when the instrument is inserted too deeply into the endocervical canal. Other sources of error include **atypical lymphocytes**, such as observed in **follicular cervicitis** (see Chap. 10), cells of **malignant lymphoma**, or metastatic cancer composed of small cells (see Chap. 17). Mitchell and Medley (1995), in a careful comparative study, documented that the small-cell malignant lesions are the **main cause of false-negative smears**. Small-cell lesions, missed on screening or misinterpreted, are **the most common reason for legal cases against laboratories**. In several personally observed cases, the failure to identify the small cancer cells led to invasive cancer within a few years.

The diagnostic dilemmas are not necessarily limited to cytologic presentation. Biopsies may also be the cause of diagnostic delays. A case in point is the patient shown in Figure 11-59, whose cytologic diagnosis of small-cell carcinoma (Fig. 11-59A,B) resulted in a first biopsy showing herpetic cervicitis (Fig. 11-59C), which was accepted as the cause of an erroneous cytologic interpretation. One year later, after another positive smear, the biopsy was repeated, disclosing a superficially invasive squamous carcinoma (Fig. 11-59D). We also observed cases with small fragments of carcinomas, either missed in the biopsy material or misinterpreted as "metaplasia," particularly in scanty endocervical curettings.

Similar small malignant cells may be observed in the so-called **tubal metaplasia**. As discussed in Chapter 10,

P.346

the presence of such cells strongly suggests the presence of a **malignant process involving the ciliated epithelium** (Fig. 11-60).

Figure 11-58 HGSIL composed of small cells. *A,B.* Clusters of tiny cancer cells that are easily mistaken for leukocytes or endometrial cells or may be entirely overlooked on screening. *C.* Cluster shown in *B* under high magnification to document granularity of chromatin and the presence of nucleoli. *D.* The histologic features of the corresponding tissue lesion composed of small cells with extension to endocervical glands.

Mixed Types of High-Grade Squamous Intraepithelial Lesions

Clear-cut cytologic identification of the three principal types of high-grade lesions is not always possible. **Intermediate and mixed forms may occur. The presence of dysplastic (dyskaryotic) squamous cells of the superficial and intermediate variety**, next to the small cancer cells, is **suggestive of a simultaneous involvement of the transformation zone and of the squamous epithelium of the portio by a lesion composed of larger cells that may be either low- or high-grade**. Another important and not unusual combination is that of an **epidermoid carcinoma in situ and endocervical adenocarcinoma**, to be discussed in Chapter 12.

RAPIDLY PROGRESSING PRECANCEROUS LESIONS

Within recent years, sporadic observations were reported on rapidly evolving invasive carcinomas of the uterine cervix, usually developing in young women within a year or two after a negative cervical smear (summary in Hildesheim et al, 1999). Consequently, several observers suggested that, in some women, invasive cancer of the cervix develops rapidly, without going through a detectable precancerous stage. In my judgment and experience, this concept is not correct. Provided that prior cytologic samples were reasonably adequate, review of the previous "negative" cytologic samples **nearly always** reveal at least a few abnormal

cells. Quite often, there is substantial evidence of a precursor lesion or cancer that was either missed on screening or misinterpreted. **Although it may be true that some precancerous lesions of the uterine cervix, such as a small-cell carcinoma in situ, may have a relatively short evolution of perhaps 5 years, they are usually detectable in cervical cytologic samples for some years before invasion occurs.** This has been documented in a multi-institutional study of high-grade lesions wherein it has been shown that cancer cells were present in a substantial proportion of previously "negative" smears (Koss et al, 1997). Several other papers and evidence addressing the issue of "false-negative" smears in women developing high-grade lesions or invasive cancer are discussed below. Similar observations were reported by Wain et al (1992) who denied the existence of "rapid onset

P.347

cancer" by finding cancer cells on review of previous "negative" smears.

Figure 11-59 HGSIL composed of small cells missed on first biopsy. *A,B.* Clusters of small cancer cells observed in the original smear. *C.* Endocervical biopsy showing herpetic endocervicitis with ulceration. This was followed by another positive smear and another biopsy one year later. The second biopsy (*D*) showed invasive squamous carcinoma.

INTERVAL CANCERS

A concept similar to "rapidly progressing lesions" is **interval cancers**, that is, carcinomas of the uterine cervix, occurring after a negative screening result. Mitchell et al (1990) reported on 138 such patients developing invasive cancer of the cervix within 36 months after one or more negative cervical smears. On review of the negative smears, all but 11.9% showed either evidence of cytologic abnormality or suboptimal sampling (absence of endocervical or metaplastic cells). Thus, the concept of "**interval cancer**" is not

P.348

valid in most cases, as it is caused, as the "rapid onset cancer," by **failures of the screening system**.

Figure 11-60 A malignant lesion arising in a focus of tubal metaplasia of the endocervix. *A.* The smear pattern composed of medium-sized cancer cells. *B.* Endocervical biopsy with a striking number of mitotic figures.

SPECIAL CYTOLOGIC PRESENTATIONS OF SQUAMOUS INTRAEPITHELIAL LESIONS

Cytolysis

Extensive cytolysis caused by *Lactobacillus* (Döderlein) (see Chaps. 8 and 10) may **destroy the cytoplasm of the abnormal cells** to the point where the nuclei of such cells are surrounded only by a narrow rim of residual frayed cytoplasm (see Fig. 11-66). Cytolysis is most commonly observed during pregnancy but may also occur in a nonpregnant woman (Fig. 11-61). **The cells most commonly affected are intermediate squamous dysplastic (dyskaryotic) cells, although occasionally, larger, more mature squamous cancer cells may be so affected.** The cytologic diagnosis may prove very difficult under these circumstances and is based mainly on **comparison of nuclear sizes and degree of nuclear hyperchromasia** between normal and abnormal nuclei.

Postmenopausal Atrophy

Most lesions observed in this age group are **high-grade intraepithelial squamous lesions** (HGSIL) or invasive carcinoma. As discussed in Chapter 8, the interpretation of atrophic smears is a common source of diagnostic difficulty. Atrophy of the vaginal and cervical epithelia and the resulting changes in cell pattern caused by dryness have a major impact on neoplastic cells. **The crisp appearance of the well-preserved dysplastic or cancer cells is often lost and the cells appear enlarged and smudgy. Their nuclei, flattened and spread over a larger area, lose some or all of their hyperchromasia and appear relatively pale, and often their internal structure is no longer discernible** (Fig. 11-62). The diagnosis is reached mainly by careful comparison of the abnormal cells with adjacent dry, but normal, squamous cells and an **assessment of the relative nuclear hyperchromasia and altered nucleocytoplasmic ratio**. Using a readily recognized landmark (such as a polymorphonuclear leukocyte) to compare with abnormal cells, is also helpful in estimating the degree of cellular and nuclear enlargement. In most such cases, a careful review of the entire preparation will usually reveal a few well-preserved cancer cells, clinching the diagnosis.

Figure 11-61 A,B. Carcinoma in situ in cervical smear of a patient in the 8th month of pregnancy. Note the extensive cytolysis.

Rarely, LGSILs may occur in postmenopausal women, sometimes at age 80 or even 90. Cytologic samples in such cases may display **koilocytes** and, hence, the features of the permissive human papillomavirus (HPV) infection (Fig. 11-63). It is not known whether the presence of active viruses represents a newly acquired infection, somewhat unlikely but not impossible, in patients of any age, or a persistence or a reactivation of an old, occult infectious process, as discussed in Part 1 of the chapter. In keeping with my experience, Rader et al (1999) reported that, in women age 55 or older, low-grade squamous neoplastic lesions of the cervix **are relatively uncommon and may be represented in smears only by atypical cells (ASCUS).**

Occasionally, a **markedly atrophic benign smear with extreme degree of cell distortion** (including the presence of elongated, spindly squamous cells) **may suggest the presence of cancer, even to an experienced observer** (see Chap. 8). Under these circumstances, a **comparison of nuclear sizes among the epithelial cells** is necessary. If the nuclear sizes of the suspect cells are identical or closely similar to those of other, clearly benign cells, the diagnosis of carcinoma is not warranted. If some of the suspect cells in the smear show considerable nuclear enlargement and hyperchromasia, the possibility of a malignant lesion may be entertained. An atrophic smear may also contain the **benign “blue bodies”** (see Chap. 8), which may imitate cancer cells to perfection.

In spite of the accumulated experience, there are situations where lingering doubts will persist as to whether an atrophic smear is benign or contains cells suspicious of cancer. In such uncommon cases, there are several approaches available. Perhaps the simplest solution is to refer the patient for **colposcopic evaluation and possible biopsies**. Alternately,

the patient may be given a **short course of estrogens** and the smear repeated after restoration of the epithelium, as discussed in Chapter 9. This latter procedure carries with it the risk of a false-negative second smear in the presence of an important lesion, as will be set forth below. The role of **HPV testing** in such situations has not been determined but may perhaps be useful (see below).

Figure 11-62 HGSIL in an atrophic smear, compared with a negative smear. *A.* Negative smear with pattern of atrophy and some nuclear enlargement, shown in *B.* *C.* Malignant cells in an atrophic smear, characterized by very large, flattened, and semitransparent nuclei. Compare with *B.* *D.* Tissue lesion corresponding to *C* showing a HGSIL.

Figure 11-63 A,B. Dysplastic (dyskaryotic) cells and koilocytes in a smear from a woman age 90 receiving estrogens. The smear with estrogenic pattern contains several koilocytes with enlarged dark nuclei and perinuclear halos.

Interpretation of Biopsies in Postmenopausal Women

High-grade precursor lesions may present a problem of recognition, not only in cytologic samples, but also in biopsies. **Most of the high-grade lesions in biopsies are morphologically identical to those seen in young women. In a number of such cases, however, the lesions undergo**

P.350

atrophy, in keeping with the general atrophic status of the epithelia of the lower genital tract. In such women, the smears may contain fairly well-preserved and recognizable dysplastic (dyskaryotic) and cancer cells, whereas **the tissue biopsies show effects of atrophy.** In some cases, only **fragments of atrophic CIN** may be observed (Fig. 11-64). In other cases with clearly positive smears, the atrophic malignant epithelium in biopsies mimics squamous metaplasia (Fig. 11-65). The spacing of the abnormal nuclei increases and there is no nuclear overlap, usually observed in younger women. The atrophy may even extend to endocervical glands (Fig. 11-65D). We have also observed cases of HGSIL in postmenopausal women wherein the smear contained **strips and fragments of malignant epithelium removed by energetic sampling.** The biopsies in such cases may show only denuded surface or small fragments of atrophic malignant epithelium difficult to interpret and considered a “crushing artifact.” Such events may be interpreted as “false-positive smears” (see below).

Some epithelial abnormalities occurring predominantly in postmenopausal women with

suspicious cytologic findings were described in histologic material as **transitional cell metaplasia** (Egan and Russel, 1997; Weir et al, 1998). In these lesions, **the characteristic features of the urothelium**, discussed at length in Chapter 22, **have not been documented, beyond a vague morphologic similarity**. In biopsies of such lesions, the nuclear abnormalities are evident but are not striking and there is some flattening of the surface, vaguely reminiscent of the urothelium. On further search, more classical high-grade lesions usually can be identified either on recuts or in adjacent segments of the epithelium. In my experience, the “**transitional cell metaplasia**” **represents atrophic HGSIL in most, if not all, cases**. As is shown in Figure 11-66, **these lesions are capable of progression to invasive cancer**. Interestingly, the smears in such cases may or may not show atrophic changes but virtually always show abnormal cells. For comments on vaginal lesions in postmenopausal women with atrophic smears, see Chapter 14.

Figure 11-64 High-grade CIN in an 84-year-old woman with marked atrophy of the malignant epithelium. A,B. Small clusters of cancer cells. **C,D.** The corresponding biopsy fragment with marked atrophy of the fragmented high-grade lesion.

Pregnancy

The cytologic diagnosis of squamous intraepithelial lesions in pregnancy may represent a challenge, for reasons discussed and illustrated in Chapters 8 and 10.

Abnormalities caused by the presence of decidual cells, the Arias-Stella phenomenon, or florid, atypical squamous metaplasia may be mistaken for malignant processes. On the other hand, pregnancy, which nearly always places the woman under the care of a physician, is a particularly beneficial time to search for cervical cancer. This is especially true of multiparae, who were shown on several epidemiologic

P.351

surveys to be more apt to develop cervical cancer than nulliparae.

Figure 11-65 Another example of a HGSIL occurring in a postmenopausal woman with epithelial atrophy. A,B. Clusters of cancer cells. **C.** A strip of atrophic CIN that may be mistaken for metaplasia. **D** shows that the atrophy extended to the endocervical glands.

In the 1950s, several observers reported that precursor lesions, diagnosed by biopsy as carcinomas in situ during pregnancy, could not be found postpartum, leading to the suggestion that these lesions were not "true" in situ cancers but "an epithelial alteration associated with pregnancy and similar to in situ carcinoma" (Schleifstein, 1950; Nesbitt and Hellman, 1952). Subsequently, Marsh and Fitzgerald (1956), Greene and Packham (1958) and many others, demonstrated that **carcinoma in situ (HGSIL), observed during pregnancy, is identical to lesions in nonpregnant women**. Personal observations support these latter views. In some patients with precancerous lesions followed for several years, pregnancy occurred while the patient was under observation (Koss et al, 1963). There was no substantial regression of the lesions (see Fig. 11-27), a view shared by Boutselis (1972). In a major review by Hacker et al (1982), the similarity of the precursor lesions and of invasive cancer in pregnant and nonpregnant women was confirmed. Coppola et al (1997) observed persisting CIN II or III in 20 of 25 women post-partum. Inexplicably, a paper by Yost et al (1999) revived the old controversy. These authors, reporting on 153 pregnant patients, observed regression of about 70% of precancerous lesions after delivery.

In my judgment, **the association of precursor lesions of cervical cancer with pregnancy is purely coincidental**. It is entirely consistent with our present knowledge of behavior of precancerous lesions, to believe that biopsies of the cervix, the trauma of delivery, or instrumentation may well account for the disappearance of some of these lesions. Because pregnant women are immunosuppressed to some extent, the high frequency of transient HPV infection (with subsequent recovery) may account for some of these observations (see Part 1 of the chapter).

Conservative approach to the evaluation and treatment of precursor lesions observed during pregnancy was stressed in a major contribution from Sweden by Hellberg et al (1987). Jain et al (1997) considered progression of LGSIL to HGSIL to be unusual during pregnancy and also advocated conservative approach to treatment.

Although **the treatment of precursor lesions can usually be postponed until post-partum, in rare cases, I observed a rapid progression of such lesions to invasive cancer** (Fig. 11-67). Therefore, if conservative approach is chosen, a very careful surveillance of pregnant patients with abnormal smears and biopsies is advocated.

Lesions in Teenagers

Sexually active adolescent girls and very young women may harbor precancerous lesions of the uterine cervix

P.352

and occasionally invasive carcinoma. The prevalence of histologically confirmed precancerous lesions in young patients varied from 2.7 per 1,000 to as high as 24.3 per 1,000 (Table 11-10) and, to my knowledge, has not changed in recent years. Studies of sexually active young women strongly suggest that this group of women often harbor an active **HPV infection** of low- and high-risk types that **is usually transient** (see Part 1 of the chapter). Thus, **HPV testing of this group of patients is not reliable and should not be used to identify patients at high risk. The discovery of precancerous lesions and cancer in this group must rest on cytologic and histologic findings.** Other sexually transmitted diseases, such as trichomoniasis, gonorrhea, and herpes, may be uncovered in such patients.

Figure 11-66 Examples of atrophic malignant epithelium mimicking the so-called transitional cell metaplasia. A,B. Sheets of atrophic epithelium with minimal nuclear abnormality. **C.** Adjacent fragments of epithelium showing atrophic CIN. **D.** A focus of

invasive carcinoma adjacent to *C*. (Case courtesy of Dr. C.M. Lombard, Los Altos, CA.)

In a study performed in our laboratories at Montefiore Medical Center, biopsy-confirmed cytologic abnormalities suggestive of CIN grade I or II were observed in 14 (3.4%) of the 403 delinquent girls ages 12 to 16, detained in custody of law-enforcement, who agreed to be tested. Twelve of the 14 abnormal smears contained koilocytes, hence, evidence of permissive human papillomavirus infection (Hein et al, 1977). It was of particular interest that the period of sexual activity preceding CIN was exceedingly short, only a few months in some girls and less than two years in others, again consistent with HPV infection. No follow-up information could be obtained on these patients. Rader et al (1997) also reported a high rate of "dysplasia" in young women with cytologic diagnosis of ASC-US.

Lesions in Immunodeficient Women

Infection with human immunodeficiency virus (HIV 1) and AIDS are additional risk factors for very young women. Maiman et al (1990, 1991) reported a high rate of cervical lesions, and even invasive cancer, in very young patients with impaired immunity caused by these conditions and resulting in an altered CD4 to CD8 lymphocyte ratio. Similar observations were reported by Feingold et al (1990), Wright et al (1994), and Ellenbrock et al (2000).

MICROINVASIVE CARCINOMA

Definition and Clinical Data

Microinvasive carcinoma was initially defined by the International Federation of Gynecologists (FIGO) as a clearly invasive epidermoid carcinoma of the uterine cervix in which the depth of invasion of the stroma did not exceed 5 mm. Subsequent careful studies by Van Nagell (1983) established that

P.353

lesions with invasion deeper than 3 mm were capable of metastases. Hence, the current definition of microinvasive carcinoma, recommended by the Society of Gynecologic Oncologists, is **invasive cervical cancer with depth of stromal invasion not greater than 3 mm** (Fig. 11-68). I feel that the above definition is deficient because it does not address the issue of the volume of microinvasion. **If the invasion is limited to one or two tongues of cancerous tissue penetrating into the stroma**, metastases do not occur. If, however, there are **multiple points of penetration into the stroma**, even if the invasion is limited to **2 mm**, metastases to pelvic lymph nodes occasionally may be observed and the lesion must be considered and treated as an occult invasive carcinoma of the cervix. Ng and Reagan (1969) reported that unicentric invasion in microinvasive carcinoma was observed in only 7.5% of cases.

Figure 11-67 Progression of HGSIL to invasive carcinoma during pregnancy. *A*. Smear obtained during the second month of pregnancy showing a few scattered dysplastic cells. *B*. Smear obtained during the 4th month of pregnancy showing a cluster of cancer cells. *C*. Biopsy obtained immediately following the smear shown in *B* showing a well-differentiated HGSIL. There was no evidence of invasion. *D*. The patient received a Caesarean section in the seventh month of pregnancy. At that time, cervical biopsies

showed an invasive carcinoma.

The decision as to **whether or not a precancerous lesion is invasive** is sometimes very difficult in biopsy material, particularly when dealing with lesions with “pushy” borders. Several studies from our laboratories examined potentially useful markers to determine invasion in SIL (squamous intraepithelial lesion). Thus, Iskaros and Koss (2000) studied the expression of the **matrix protein tenascin** and suggested that its increased expression may be suggestive of invasion. Oktay et al (2003) studied **focal adhesion kinase (FAK)** with similar results. In the cases studied by Oktay, the expression of human papillomaviruses type 16 or 18 was not related to the expression of FAK.

Microinvasive carcinoma is generally asymptomatic, does not produce visible changes on the surface of the cervix and, therefore, its discovery is incidental to the search for precursor lesions. Ng and Reagan reported that

P.354

the average age at the time of discovery of microinvasive carcinoma is 6 years less than for fully invasive cancer. By serial or step sectioning of tissue blocks with precursor lesions, a number of **unsuspected microinvasive carcinomas** may be uncovered, ranging from 4.7% (Killackey et al, 1986), to 6% (Fidler and Boyes, 1959), to 8.4% (Ng and Regan, 1969). Such lesions are generally **considered to be of biologic interest rather than practical importance** because they can be successfully treated by LEEP (loop electrosurgical excise procedure) conization.

Figure 11-68 A,B. Examples of microinvasive carcinoma.

Cytology

In 1972, Ng et al suggested that a cytologic diagnosis of microinvasive epidermoid carcinoma of the uterine cervix can be made with a high degree of accuracy. These observers reported the following cytologic criteria of microinvasion based on a study of 52 patients:

- Presence of inflammation and necrosis (“tumor diathesis”) in two-thirds of the cases
- Occurrence of most (75%) malignant cells in aggregates (“syncytia”)
- Irregular distribution of nuclear chromatin in 50% of the cancer cells
- Presence of prominent nucleoli in 20% of the cancer cells

The same authors performed a planimetric study of cancer cells in microinvasive carcinoma, compared with cells from carcinoma in situ and fully invasive carcinoma. A number of features including cell area, nuclear area, several nuclear descriptors, and the total number of nucleoli per cell were intermediate between the two other lesions.

Subsequent studies were conflicting as to whether cytologic features are reliable in separating microinvasive carcinoma from a high-grade precursor lesion or invasive cancer. Thus, Rubio (1974) was unable to confirm Ng's data, whereas Nguyen (1984) was in partial agreement. In a more recent study of cervical smears in 28 patients with microinvasive carcinomas from the Netherlands, 2 lesions were missed, 3 were diagnosed as LGSIL (CIN I or II), 15 as HGSIL (CIN III), and 8 as “carcinoma” (Kok et al, 2000). There are no studies of this topic using liquid collection method.

Microinvasive carcinomas, in which the invasion is confined to one or two tongues of cancerous tissue invading the stroma, particularly those originating from low-grade lesions, are extremely unlikely to shed specific cell types suggestive of early invasion. **The lesions, with multiple foci of superficial invasion, may occasionally show smear patterns that are intermediate between a high-grade lesion (HGSIL) and invasive carcinoma. Such smears often contain a large number of dysplastic (dyskaryotic) and cancer cells,**

corresponding to a large lesion, and evidence of necrosis and inflammation. One can also encounter, in such smears, **bizarre cell forms and a relatively large number of cancer cells with prominent nucleoli**, especially if the lesion is of endocervical derivation. For many years now, smears of this type have been classified in our laboratories as "squamous" or "epidermoid carcinoma—cannot rule out invasion," presumably an equivalent statement to Ng's "microinvasive carcinoma." The histologic findings in such cases were variable; about half of the patients harbored HGSIL without invasion, whereas in the remaining cases, varying degrees of invasion, including rare fully invasive carcinomas, were observed. Thus, in my experience, **the cytologic concept of microinvasive carcinoma has limited validity in the day-to-day practice of diagnostic cytology.**

INVASIVE SQUAMOUS CARCINOMA

Clinical Data and Indications for Cytologic Sampling

The **prognosis of invasive cancer of the uterine cervix** depends on **stage** of the disease (see Table 11-3). The prognostic significance of tumor **grade** is less secure, although high-grade tumors are likely to be more aggressive. Invasion of lymphatics, metastases to regional lymph nodes, and invasion of blood vessels, may occur in all types of cervical cancer and is considered to be of **unfavorable prognostic significance**. A prognostically **favorable** feature in stage I tumors is the presence of **lymphocytic infiltrate** in the stroma (Sidhu et al, 1970). Because women with low stages of the disease have a much better chance of survival than those with more advanced carcinomas, the discovery of the lesion in the earliest possible time is important to the patient.

P.355

Hagmar et al (1995) correlated prognosis with types of human papillomaviruses; patients with HPV types 18 or 33 had a poorer prognosis and shorter survival than patients harboring other high-risk types of the virus.

Contrary to precursor lesions, which are usually not evident on visual speculum examination and require colposcopic identification, **advanced invasive cancers** of the uterine cervix usually produce **grossly visible changes** in the form of ulceration or a tumor of the cervix. Application of cytologic techniques to the diagnosis of clinically obvious invasive carcinoma is a diagnostic luxury since these lesions **should be diagnosed by biopsy**. However, many women are now first seen by family physicians or nurse-practitioners who may not have the same familiarity with the clinical presentation of invasive cancer as trained gynecologists. Consequently, some invasive cancers may pass unrecognized on clinical examination. **In such situations, listening to the patient is very important:** many women with early invasive cancer report bleeding, spotting, or dyspareunia. Still, **some invasive cancers, particularly those of low stage with intact surface and those originating in the endocervical canal, may fail to produce obvious gross changes and may be unrecognized**, even by an expert eye. An "erosion" or a reddened cervix bleeding on touch, often with some discharge, may be observed, and the diagnosis of "**cervicitis**" or "**friable cervix**" is rendered. In these situations, a cytologic sample may prove to be life-saving by establishing the initial diagnosis **but, as is common in invasive cancer, the method may fail, resulting in a further diagnostic delay**. In many of the legal cases on behalf of women with severe damage to their health or even loss of life caused by cancer of the cervix, failure to biopsy the relatively inconspicuous abnormalities was followed by a failure of cytologic examination.

Figure 11-69 Invasive squamous carcinomas of cervix. A, Well differentiated carcinoma (grade I) with formation of large keratin deposits. B, C, High-grade squamous

intraepithelial lesion with numerous koilocytes with transition to invasive carcinoma of similar configuration. *D.* Grade II squamous cancer.

Adenocarcinomas and their variants are discussed in Chapter 12.

Histology

Invasive squamous cancer generally follows the patterns of the precursor lesions and may be classified histologically into three main groups:

- **Well-differentiated (grade I), pearl-forming, keratinizing squamous carcinoma** (Fig. 11-69A). Keratin formation is the dominant feature of these tumors, which are otherwise composed of typical squamous cancer cells. As is the case with keratin-forming precursor lesions, most of these cancers **originate in the surface squamous epithelium of the cervix** and are preceded by low-grade

P.356

precursor lesions. In some of these tumors, conspicuous koilocytes may be observed (Fig. 11-69B,C). Occasionally, invasive squamous cancers may originate in **quasi-normal squamous epithelium** (Fig. 11-70). Morrison et al (2001), in describing such rare lesions, noted their aggressive behavior and lack of association with human papillomavirus. A rare variant of squamous cancer is the **verrucous carcinoma** that may grossly resemble giant condylomata acuminata of Löwenstein-Buschke type of penile lesions (see Part 1 of the chapter). These tumors, which very rarely metastasize but may be deeply invasive, show only slight nuclear abnormalities (Fig. 11-71D) and have a relatively benign course after treatment (Morrison et al, 2001).

P.357

- **Medium-sized cell squamous (epidermoid) carcinoma, grade II**, derived from high-grade lesions of metaplastic type (Fig. 11-72D). **The tumors are composed of sheets of cancer cells of relatively monotonous appearance but often contain foci of keratinizing squamous cancer, not evident in the precursor lesion** (see Fig. 11-67).
- **Small cell carcinoma, grade III**, derived from precursor lesions composed of small cells (Fig. 11-73D). The cancer cells are either arranged in nests separated by connective tissue septa or diffusely infiltrate the stroma. Some of these tumors have **endocrine function**, which is occasionally reflected in the formation of **rosette-like structures**. Still, electron microscopy and immunochemistry are required to establish their identity. In rare cases, the tumors may be **hormone-producing**. Thus, Kothe et al (1990) reported such a tumor secreting **antidiuretic hormone**. Iemura et al (1991) reported a case of **Cushing's syndrome** caused by a small-cell cervical carcinoma secreting ectopic adrenocorticotropin hormone. In a recently reported case, **hypoglycemia** was observed in a young patient with an insulin-secreting cervical carcinoma (Seckl et al, 1999). Watanabe et al (2000) reported a case secreting **granulocyte-colony stimulating factor** in a 70-year-old woman with marked leukocytosis. Herrington et al (1999) reported that, in many tumors of this type, there is a loss of retinoblastoma (Rb) gene expression. Invasive squamous carcinomas may be either "**pure**," composed of cells of only one type, or "**mixed**," containing several types of cancer side by side. For example, **focal keratinization** with pearl formation and **focal gland formation** may occur in medium- or small-cell cancers. Some of the invasive cancers may show **unusual patterns**, discussed in Chapter 17.

Figure 11-70 Invasive squamous carcinoma. An example of invasive squamous carcinoma (*A*) derived from a nearly normal surface epithelium (*B*).

Figure 11-71 Invasive squamous carcinoma. *A,B.* Extraordinary variety of squamous cancer cells in a SurePath. *C,D.* Verrucous carcinoma of cervix. *C* shows atypical squamous cells that are characteristic of this disorder. The abnormality is limited to nuclear enlargement with slight hyperchromasia. *D* shows a biopsy of the cervical lesion with markedly keratinized surface.

Figure 11-72 Invasive squamous carcinoma represented by medium-sized cancer cells. *A.* The dense cluster is composed of cancer cells of medium size. At the periphery of the cluster, some of the cancer cells are of columnar shape, an indication of endocervical origin. Note nuclear abnormalities. *B.* High magnification to show "naked" large cancer cell nuclei from an invasive carcinoma composed of medium-sized cells. *C.* Scattered cancer cells of medium size corresponding to the invasive carcinoma shown in *D*.

Some of the **difficulties in cytologic recognition of invasive squamous cancer** were illustrated by a study of 43 such lesions from the Netherlands. Seven of the smears were considered to be negative on screening, 6 were reported as low-grade lesions, 15 as high-grade lesions, and only 15 smears were reported as invasive cancer. On review, 4 of the missed smears consisted only of inflammatory exudate, necrotic debris, and blood, in which no cancer cells could be identified. In three remaining missed cases, the evidence of cancer was very scanty and limited to a few cancer cells hidden in exudate. The classical features of invasive cancer

P.358

were absent in most smears diagnosed as precursor lesions (Kok et al, 2000). Similar observations were reported by Levine et al (2003).

Figure 11-73 Invasive squamous carcinoma composed of small cancer cells. *A, B.* Clusters of tiny cancer cells easily overlooked on screening. *C.* A high-power view of one of the clusters showing irregular nuclear contour and granulation of chromatin. *D.* Tissue pattern corresponding to *A-C*.

Cytology

The cytologic diagnosis of invasive squamous carcinoma is **often more difficult** than that of precursor lesions, because the preparations may **contain necrotic material, blood, and debris**, obscuring the often poorly preserved cancer cells. The term “**cancer diathesis**” has been applied to such features, which are a reflection of necrosis of the surface of invasive tumor. In such instances, a careful examination of the preparation with frequent use of a high-power objective may be necessary to avoid errors of omission. **Not all invasive cancers show “cancer diathesis,” particularly those in early stages without surface necrosis.** In such instances, the cell sample may be difficult to interpret as invasive tumor.

Dysplastic (dyskaryotic) cells, including koilocytes, may be present in cytologic preparations from invasive squamous carcinomas and are sometimes the only evidence of disease. These cells are derived from areas of precursor lesions on the margin of invasive cancer but may also originate from the surface of a well-differentiated invasive keratinizing carcinoma. However, the predominant abnormal cells are **differentiated and undifferentiated cancer cells**, displaying marked aberrations of the nucleus and the cytoplasm (see Figs. 11-72, 11-73; see also Figs. 11-37, 11-38 and 11-39). This heterogeneous population of cancer cells is very characteristic of invasive cervical cancer (see Tables 11-8 and 11-9). **Cell necrosis, apoptosis, and aberrant mitotic figures may also be observed** in cytologic preparations (see Fig. 11-39D).

Another common feature of cytologic presentation of invasive cancer is the presence of **large sheets of cells or fragments of tumor** removed from the fragile surface, which are often too thick for a detailed microscopic study (see Fig. 11-72A). Nuclei stripped of cytoplasm (“**naked nuclei**”) are not uncommon (see Fig. 11-72B). In some cases, the large nuclei of cancer cells may be pale, bland, vesicular, and sometimes contain a single visible nucleolus (see Fig. 11-72C). **The large fragments of tumor should never be ignored or dismissed** but, rather, should be carefully examined, especially at their periphery (see Figs. 11-33C,D and 11-72A).

The cytologic identification of the three principal patterns of invasive carcinoma in smears is sometimes possible but is of limited clinical value. However, certain basic differences in cell types may be observed.

- **Keratinizing (squamous) carcinomas** shed mainly differentiated, keratinized, squamous cancer cells, some of

P.359

which may closely resemble dysplastic (dyskaryotic) cells. Koilocytes may be present. In such tumors, squamous “pearls,” spindly cancer cells, tadpole cells, and other bizarre cell types are common (see Fig. 11-37).

- **Keratinized debris (anucleated squames) may dominate the smear pattern** (see Fig. 11-39B). The extraordinary **diversity of cell types and shapes** can be very well documented in liquid preparations such as SurePath (see Fig. 11-71A,B).

It is sometimes very difficult to separate cytologically invasive carcinomas of this type from their noninvasive precursors in the absence of “cancer diathesis” because the cell populations may be so similar. Similar observations were reported by Levine et al (2003).

- The rare **verrucous squamous carcinomas** of the cervix may be **extremely difficult to recognize in the cytologic sample**. The squamous cancer cells are often very well differentiated and mimic normal squamous cells, except for some cytoplasmic keratinization and nuclear enlargement and pyknosis (see Fig. 11-71C). Cases of this tumor type shedding obvious cancer cells were reported by Fentanes de Torres and Mora (1981) and by Barua and Matthews (1983).
- The extremely rare squamous carcinomas derived from quasi-normal surface epithelium cannot be recognized in cytologic preparations.
- **The intermediate type of invasive carcinoma** often combines the features of all types of cancer cells. In some of these lesions, **dysplastic (dyskaryotic) cells of parabasal type, and medium-sized keratinized cancer cells predominate**. In other lesions, **undifferentiated cancer cells of medium sizes, singly and in clusters, form the bulk of the population of abnormal cells** (see Fig. 11-72). "Naked" cancer cell nuclei showing coarse chromatin patterns are fairly common (see Fig. 11-72B). In the majority of lesions, there is a mixture of various cell types side-by-side.
- **Small cell carcinomas** usually shed a relatively monotonous population of undifferentiated, small malignant cells, occurring singly or in small clusters (Fig. 11-73). Small columnar-shaped cancer cells are not an unusual finding (Fig. 11-73A). Such cells may display cytoplasmic vacuoles and, when numerous, the sample can be misclassified as adenocarcinoma. In the endocrine variant of this tumor, arrangement of cancer cells in rosettes may be occasionally observed but this is a very rare finding.
- As is the case with high-grade precursor lesions of small cell type, this type of invasive carcinoma causes the greatest difficulties of recognition because of the small size of the abnormal cells, sometimes obscured by blood and debris. This problem was illustrated in a paper by Zhou et al (1998) in which the cervical smears in 7 of 12 such lesions were reported as negative. On review, cancer cells were found in 2 of the 7 negative smears. The issue is discussed further below in reference to accuracy of cervical samples.

ATYPICAL SQUAMOUS OR GLANDULAR CELLS OF UNKNOWN SIGNIFICANCE: THE LEGACY OF THE BETHESDA SYSTEM

Ever since the introduction of cytologic screening over half a century ago, it has been known that there are daily instances in practice when a cervicovaginal preparation contains a few cells with relatively slight nuclear or cytoplasmic abnormalities that are difficult or impossible to interpret accurately. In the past, the term **atypia** sometimes accompanied by a comment guiding the clinician in further investigation of the patient, Papanicolaou's class II or, rarely, class III diagnoses, were used in such instances. Regardless of the system of reporting, such diagnoses created problems of clinical handling and caused anxiety in patients. In most such instances, the problem could be resolved one way or another by follow-up smears or sometimes by colposcopy and biopsies.

It must be stressed that some precursor lesions or invasive cervical cancer may be very difficult to recognize in smears with **extensive inflammation and necrosis** and may be represented by only a few abnormal cells. Some of these difficulties have been reduced by the use of liquid systems of processing.

In the original, 1991 Bethesda System, these terms have been replaced by the terms **atypical squamous cells of unknown significance (ASC-US)** and **atypical glandular cells of unknown significance (AGUS)**, thus condemning the term "atypical smear" and Papanicolaou's classification to the heap of history. It was suggested, in reference to the ASC-US diagnoses, that a preference should be expressed as to whether the smear pattern was probably benign (reactive) or probably malignant. **It seems contradictory to the definition of "cells of unknown significance" to be further classified as either probably benign or possibly malignant**. In fact, Malik et al (1999), among others, found the subdivision of ASC-US in low-and high risk groups to be of limited value. Still, the concept of ASC-US and AGUS was accepted as "national standard" in the United States by the governmental agency, Centers for Disease Control in Atlanta, Georgia.

The 2001 Bethesda System modified these recommendations. **ASCUS** was subdivided into two categories: (1) **atypical squamous cells of undetermined significance (ASC-US)** and (2) **atypical squamous cells, cannot exclude high-grade squamous intraepithelial lesion (ASC-H)** (Sherman et al, 2004; Solomon et al, 2002; Solomon and Nayar, 2004). The ASC-H classification replaces the very useful **old term "suspicious,"** for smears with a small number of abnormal cells that, in the opinion of the cytopathologist, were insufficient for a diagnostic conclusion and required further clarification. **No separate provisions were made in the 2001 Bethesda System for ASC-US samples suggestive of, or suspicious of, LGSIL, apparently in the erroneous belief that such lesions can always be recognized or that**

they are harmless manifestations of HPV infection. It was suggested that such cases should be included in the ASC-US category (Sherman et al, 2004). Pirog et al (2004)

P.360

reported that elimination of the category ASC-US-reactive improved the performance of her laboratory.

The **AGUS** category was abolished and replaced with “**atypical glandular cells of endocervical, endometrial, or unknown origin**” that are either not further specified (NOS) or accompanied by a comment (Covell et al, 2004).

The term **ASC-US** was defined by Kurman and Solomon in 1993 as the presence of **intermediate squamous cells with nuclear enlargement 2½ to 3 times above that of a normal cell**, corresponding to the definition of **karyomegaly**, discussed in the early part of this chapter (see Fig. 11-30). The term **AGUS** was vaguely defined as “**changes in the endocervical cells that are intermediate between benign abnormalities and cancerous changes.**” The latter abnormalities are discussed above in reference to squamous lesions located in the endocervical canal, and again in reference to precursor lesions of adenocarcinoma in Chapter 12. The old definition of AGUS did not mention cells of endometrial origin, discussed in Chapter 13.

Kurman and Solomon suggested in 1993 that the rate of ASC-US in a laboratory should not be higher than 2 to 3 times the rate of SIL. The source of this statement is not clear. However, in a survey of a large number of laboratories conducted by the College of American Pathologists, the rate of ASC-US was 2.8%, whereas the rate of SIL was 2.0% (Davey et al, 1996). In a subsequent survey, the rate of ASC-US rose to 5% (Davey et al, 2000).

As discussed in reference to karyomegaly, the definition of ASC-US, as proposed by Kurman and Solomon, is difficult to apply because it is subjective and limited to large squamous cells. For example, the presence of 6 or more such cells may indicate the presence of a squamous neoplastic lesion, usually LGSIL. The terms **ASC-L or “suspicious,” are lacking in the Bethesda System. This is important inasmuch as significant lesions may be hiding behind the relatively insignificant cell abnormalities, as documented above.** Further, karyomegaly is not the only abnormality of note that may be difficult to interpret.

The term **ASC-H**, as illustrated by Sherman et al (2004), apparently pertains to **small dysplastic (dyskaryotic) cells** that should have been recognized as malignant (see Fig. 11-34) and to **metaplastic cells with enlarged nuclei** that may be the precursor of high-grade lesions (see Fig. 11-38). To be sure, in some cases, particularly in liquid preparations resulting in dispersion of such cells, the firm diagnosis cannot be established and requires further follow-up. The old term “suspicious” or class III smears corresponded to such findings.

Few events in the history of diagnostic cytology have had an impact as marked as the introduction of the terms ASC-US and AGUS. Dozens of papers have been published on this subject, mainly documenting that the **definitions are too vague to be universally accepted** and are not reproducible (Schiffman and Solomon, 2003; Confortini et al, 2003). Smith et al (2000) reported that a review of the Bethesda System Atlas by Solomon and Kurman (1993), by a panel of pathologists, did not improve the reproducibility or accuracy of classification of ASC-US. In fact, the **terminology has contributed significantly to the cost of cancer detection** by proposing expensive solutions, such as HPV testing (see below) that, so far, have not been shown to improve the detection system and reduce the mortality from cervix cancer in a documented fashion.

There are several reasons for the diagnosis of atypical smears, or its current Bethesda System equivalents. **Probably the most common cause for these diagnoses lies in the observer's lack of experience, timidity, or inability to identify accurately the cytologic patterns.** Sherman et al (2003) reported that among 171 women with documented CIN III or cancer 123 or 72% had initial smears classified as ASC-US, strongly suggesting that either the screening or the interpretation of this material was faulty. Zonky et al (1999) noted that 77% of high-grade lesions and invasive cancer were found after “minor” smear abnormalities. The term is also used as a **defensive measure** to avoid a potential legal entanglement (Austin 2003). In 2003, Schiffman and Solomon estimated 2 million cervical preparations will be classified as ASC-US in the United States.

There are instances, however, in which the diagnosis is justified because of cell changes that are difficult to classify. Some sources of atypical smears encountered over the years are listed below.

Abnormalities That Could Be Classified as ASC-US

- Karyomegaly: moderate or marked nuclear enlargement without marked hyperchromasia, limited to a few intermediate or large parabasal squamous cells (see discussion of

karyomegaly in the opening pages of the second part of this chapter)

- Cytoplasmic vacuolization in intermediate squamous cells, suggestive, but not diagnostic, of koilocytosis (see Fig. 11-31D)
- Pattern of advanced atrophy of the cervix and vagina, particularly in the presence of “blue bodies,” mimicking cancer cells (see Chap. 8)
- Inflammatory events, resulting in slight nuclear enlargement and pyknosis and slight irregularities of nuclear shape, such as observed in severe infestation with *Trichomonas vaginalis* or in herpetic infections (see Chap. 10)
- Metaplastic squamous cells with enlarged nuclei (see Chap. 10)
- Pattern of abnormal keratinization of squamous cells

Abnormalities That Could Be Classified as Atypical Endocervical Cells (Former AGUS)

- Endocervical cells with nuclear enlargement, slight hyperchromasia and enlarged nucleoli (see also Chaps. 10 and 12)
- Acute inflammatory and reactive phenomena in the epithelium of the endocervix, resulting in patterns of “repair” or florid metaplasia (see Chap. 10)
- Atypical, florid metaplasia (see Chap. 10)
- Thick clusters of endocervical cells (brush effect), difficult to classify (see Chap. 8)

P.361

What Should *Not* Be Classified as ASC-US or AGUS?

Over the years, we have seen a number of cervical smears diagnosed as “atypia,” ASC-US, or AGUS, that did not merit this classification because they represented definitive lesions. Some of these findings were:

- A significant number of cells with karyomegaly (more than six in my experience) or related well-differentiated dysplastic superficial or intermediate squamous cells—such smears should be diagnosed as LGSIL
- Heavily keratinized squamous cells with somewhat enlarged, pyknotic nuclei that usually represent a kerat-informing malignant process
- Small dysplastic (dyskaryotic) cells, sometimes mimicking metaplastic cells, which should be classified as HGSIL
- Dense clusters (“syncytia”) of small or large dysplastic (dyskaryotic) cells or cancer cells that represent a HGSIL or even invasive cancer

There are also benign abnormalities, discussed in Chapters 8 and 10, that may mimic a malignant lesion. Chief among them are:

- Pregnancy changes (see Chap. 8)
- Atrophic smears with atypia caused by dryness or containing “blue bodies”

Follow-up Studies of ASC-US, AGUS, or “Atypical Smears”

Before the introduction of the terms ASC-US and AGUS, there were several **follow-up studies** of patients with **atypical smears**. As early as 1976, Melamed and Flehinger reported a follow-up study of 1,973 women attending the Planned Parenthood clinics in New York City with “atypias” of squamous cells in cervicovaginal smears. The “atypias” were defined as **abnormalities of squamous cells not attributable to inflammation, yet not sufficient to establish the diagnosis of a neoplastic lesion**. The results documented that **“atypia” was a risk factor in the development of precancerous lesions of the cervix**. The probability of a neoplastic event in these women was calculated at 5 to 10 times higher than for women with negative smears. Women with **two sequential atypical smears had an approximately 10 times higher probability of subsequent CIN**.

The limited clinical value of the term **atypia** was brought sharply into focus by several older clinical studies. Scott (1964) and Nyirjesy (1972) recognized that hiding behind this terminology was a broad variety of important neoplastic events such as CIN, and occasionally, invasive cancer. Benedet et al (1976) reported that, among 320 patients with “Class II” smears (a numerical equivalent of benign atypia) there were 135 (42%) “dysplasias” of various degrees and 83 (25%) carcinomas in situ. Jones et al (1987) found 25% of CIN in 236 patients with diagnosis of “atypical” smears. Frisch et al (1987, 1990) pointed out that 12% of cervical smears from 200 young college students, diagnosed as “inflammatory epithelial changes,” concealed CIN. The unifying theme of these studies was that **a substantial proportion of**

women, ranging from 12% to 25%, with a cytologic diagnosis of “atypia” or “inflammatory changes,” harbor precancerous lesions or invasive cancer of the uterine cervix that can be detected by colposcopy and biopsies.

Since the introduction of the Bethesda System, numerous papers reported the results of follow-up studies of patients with the cytologic diagnosis of ASC-US; in nearly all of them, some of the patients were shown to harbor squamous neoplastic lesions, usually of low-grade (70% to 95%) but some of high-grade, or even invasive cancers (Sidawy and Tabbara, 1993; Davey et al, 1994; Selvaggi and Haefner, 1995; Williams, 1997; Sidawy and Solomon, 1997). There are **significant differences in the percentage of HGSIL, invasive cancer reported in recent years from different laboratories**. The range is from none (Gonzales et al, 1996), 1% to 2% (Kobelin et al, 1998; Ettler et al, 1999; Malik et al, 1999; Sherman et al, 1999) to 9% or more (Kaufman, 1996; Auger et al, 1997; Nyirjersy et al, 1998; Raab et al, 1999). Rader et al (1999) pointed out that diagnosis of **ASC-US** in women age 55 or older is relatively uncommon (1.8% of 8,175 smears) but may also lead to the discovery of neoplastic lesions, ranging from LGSIL to invasive cancer, albeit in a lesser proportion than in younger women. In a very large Norwegian study of more than 500,000 women with 7 years of follow-up, Nygaard et al (2003) reported that women with ASC-US were 15 to 30 times more likely than normal women to develop a CIN III or invasive cancer of the cervix. Dvorak et al (1999) recommended an aggressive follow-up for women with ASC-US or LGSIL because of the large number of high-grade lesions hiding behind these diagnoses.

The disparities of the results from the various centers may be a reflection on the **population studied, definition and usage of the term ASC-US, the performance of the laboratory, and its philosophy of reporting “non-normal” material**. Some of these differences may be based on divergent interpretation of biopsies that varies from observer to observer and from laboratory to laboratory (Grenko et al, 2000).

It is of interest that the **high-grade lesions, observed in patients with ASC-US, are often very small in size and of questionable clinical significance** (Pinto et al, 2002; Sherman et al, 2003). Figure 11-74A summarizes the findings in ASC-US.

The AGUS category was abolished in the 2001 Bethesda System because of a very high rate of malignant events in this group of patients, summarized in Figure 11-74B, courtesy of Dr. Mary Sidawy. Although the abnormal cells were of endocervical type, the frequency of **SIL was significantly higher than that of adenosarcomas**, as previously discussed in this chapter. Bose et al (1994) reported 17 LGSIL, 18 HGSIL in 44 women whose smears were diagnosed as AGUS. Lee et al (1995) reported that the diagnosis of “severe glandular atypia” corresponded, in 26% of patients, to an endocervical adenocarcinoma and, in 53% of patients, to HGSIL. In patients diagnosed as

P.362

“mild glandular atypia,” follow-up studies disclosed 2.5% adenocarcinoma in situ, 35% of HGSIL, 2.5% of LGSIL, with the remaining cases showing no significant lesions. Samsir et al (2003) reported that there is a very limited consensus among competent observers in classifying atypical glandular cells. **A particularly unfortunate diagnosis of AGUS is based on the finding of “atypical metaplasia,” which, in most cases, represents a high-grade squamous lesion of endocervical origin, as discussed above**. For further discussion of AGUS as a precursor lesion of endocervical adenocarcinoma, see Chapter 12.

Figure 11-74 A A diagrammatic drawing showing the proportion of high-grade lesions in smears designated as ASC-US. The number of high-grade malignant lesions is small. B. A diagrammatic drawing showing the outcome of smears diagnosed as AGUS. The number of malignant lesions is much higher than in the ASC-US series. (Courtesy of Dr. Mary Sidawy, Washington, DC.)

It is evident that the diagnoses of ASC-US, AGUS, or the equivalent term, **atypical smears**, is widely used but **should be avoided at all cost. In many such instances, a careful rescreening of the preparation or a consultation with a competent colleague may be helpful in eliciting a definitive diagnosis of either a benign lesion, CIN, or even invasive cancer.**

Still, in every laboratory, there is a **small residue of adequate cervical preparations that cannot be definitively classified because of scarcity of abnormal cells or because of cell changes that are difficult to interpret, that can justifiably be reported as ASC-US or AGUS.** Pitman et al (2002) reported that the abolition of AGUS would lead to a loss of about one-half of HGSILs. The current clinical approaches to the handling of such patients, including HPV typing, are discussed below.

REPRODUCIBILITY OF CYTOLOGIC DIAGNOSES IN CERVICAL SAMPLES

The interpretation of cytologic pattern in adequate cervical smears is often a major problem. There is a similarity here with mammography, another test based on visual assessment (Elmore et al, 1994). As has been documented in early studies by Seybolt and Johnson (1971), Koss (1982), Yobs et al (1985, 1987), Klinkhamer et al (1988), and others, **the reproducibility of cytologic diagnosis among various otherwise competent observers is low.**

The situation has not changed in recent years. Stoler and Schiffman (2001) observed only moderate reproducibility in the interpretation of liquid preparations (kappa value 0.46, 1 being complete agreement). Renshaw et al (2003), based on a very large number of responses from practicing pathologists, observed that the reproducibility of diagnoses was somewhat better for benign smear patterns and low-grade squamous lesions (LSIL) than for high-grade lesions (HGSIL) and invasive cancers. In 2004, Renshaw et al analyzed these results further and noted that the cell patterns in some invasive cancers were interpreted as "reparative," particularly in the presence of *Trichomonas* infestation. The problem lies often in philosophic approach to smear interpretation that separates the "conservative" from "aggressive" observers. Although the criteria for classification of cytologic samples may be verbalized and the key findings illustrated, as was done in the preceding pages, **the application of these principles depends on the training, experience, and talent of the observer.** Further, the infinite variety of morphologic patterns that may be observed in cervical samples often defies the classical standards of diagnosis. **The cytologic patterns that are most often underestimated are those of keratin-forming lesions, small-cell carcinomas, and invasive carcinomas of various types.** Also, smears containing only a few abnormal dysplastic (dyskaryotic) cells, as is often the case, are often undercalled and placed in the category of ASC-US.

P.363

The **reproducibility of diagnoses by the same observer** at various time intervals is also low. This was documented in an unpublished study by Wied, who submitted the same set of cervical smears to a group of expert cytopathologists (including this writer) at 6 month intervals. Quite often, on the second review, the observers disagreed with their own prior diagnosis. It is generally easier to achieve reasonable consistency of diagnoses among members of the same group than among different laboratories.

CORRELATION OF BIOPSIES WITH CYTOLOGIC PATTERNS

Although biopsies have been often considered to be the "gold standard" against which the cytologic diagnoses should be measured, **this is often not the case.** To be sure, errors in the assessment of cytologic samples do occur but there is evidence that, **in a significant proportion of cases, biopsy sampling and the interpretation of tissue patterns are often inaccurate and not necessarily superior to cytology.** Tritz et al (1995) reported discrepancies between cytologic and histologic diagnoses in 69 (11%) of 615 patients with a cytologic diagnosis of a neoplastic abnormality. **The most common source of error was inappropriate biopsy that missed the lesion in 51%, followed by faulty biopsy interpretation that occurred in 13% of the discordant cases.** Similar observations were reported by Joste et al (1995), Rasbridge and Nayagam (1995) and Stoler and Schiffman (2001).

Jones and Novis (1996) studied the **correlation of diagnoses** rendered on cervical **smears with biopsies** in 348 American laboratories. In 22,439 paired smears and biopsies, the **sensitivity of cytologic findings** was 89.4%, **specificity** 64.8% and **predictive value** of positive cytology 88.9%. It was noted that the knowledge of results of cytology improved the accuracy of biopsy interpretation. There is also **extensive documentation** that the interpretation of biopsies **may vary from one observer to another.** In a classical study, Siegler (1956) selected 20 biopsies of the uterine cervix, showing fairly classical carcinoma in situ (HGSIL) to 25 pathologists. Approximately half of the diagnoses were missed by the

participants, with some failing to recognize any of the lesions. Although the study was conducted before widespread use of cervical smears and may be, in part, explained by limited exposure of pathologists to these lesions, the observations were confirmed in later years by Holmquist et al (1967), Cocker et al (1968), and Robertson et al (1989). These problems persist until today (year 2005). In a recent study of difficult-to-interpret biopsies showing "atypical immature metaplastic proliferations," the diagnostic concordance between two observers working in the same laboratory as to the benign or malignant nature of these lesions was, at best, mediocre (Park et al, 1999). Grenko (2000) also reported lack of agreement among experienced pathologists in the interpretation of cervical biopsies.

There are **several situations where a biopsy can be misinterpreted or the lesion missed**. These are listed below:

- Inadequate sampling of the cervix by inexperienced colposcopists. This is particularly important when the lesion is located in the endocervical canal.
- Interpretation of endocervical curettings, wherein tiny fragments of a high-grade lesion are readily overlooked.
- Interpretation of endometrial curettings containing fragments of a squamous malignant lesion, derived from the uterine cervix, that are either overlooked or sometimes interpreted as decidual reaction.
- Interpretation of biopsies in postmenopausal women may also cause difficulties, particularly when the fragments of CIN are atrophic. As has been stated above, the term "transitional cell metaplasia" is a misnomer in the interpretation of atrophic CIN lesions in this group of patients.
- An important source of errors is inadequate training in the interpretation of cervical biopsies which is prevalent among pathologists who have no experience with cytology of the cervix or those who were instructed that the interpretation of intraepithelial neoplastic lesions of the cervix should be conservative in order to avoid unnecessary treatment. Many of these observers use the term "dysplasia" and strenuously avoid the use of terms such as high-grade lesion, CIN III, or carcinoma in situ.

ACCURACY OF CERVICAL SAMPLES IN THE DETECTION OF SQUAMOUS LESIONS

Preceding its introduction as a mass-screening procedure, the effectiveness of cervicovaginal cytology **as a means of detection of precancerous lesions and early cancer of the uterine cervix had never been tested in a double blind study** (Koss 1989). **The performance of the system has been judged by its effectiveness, based on epidemiologic studies, showing that the rate of invasive cancers among screened women fell by about 75%.** Because the majority of women who developed invasive cancer of the uterine cervix had no previous screening, **it has been assumed by many clinicians and by the lay public that the "Pap smear" had a high degree of accuracy.**

Further, the assumption that careful analysis of smear patterns **in satisfactory cytologic material** allows a precise **classification of the underlying precursor lesion has been incorporated into the Bethesda System**. Regrettably, this is not the case, because **the margin of error in such assessments may be substantial**, as has been repeatedly documented by a careful correlation of cytologic diagnoses with histologic material and will be illustrated below.

As early as 1964, Navratil from Graz, Austria, reported smear failure in 15% of precancerous lesions diagnosed by colposcopy. Hill (1966) reported from the same clinic that cervical smears failed in 59 (7%) of 838 cases of precancerous lesions of the cervix. A startling indictment of cytology as the tool for cervical cancer detection was presented from Sweden by Rylander (1976), who reported the Stockholm experience for the years 1968 through 1974. Of the 179 women with invasive cervical cancer, 143 had the benefit

P.364

of early competent cytologic examination. In 64 (44%) of the 144 women, earlier smears were reported as "negative." In 13 of these patients, invasive cervix cancer occurred within 1 year, in 23 within 2 years, in 17 within 3 years, and in 11 within 4.5 years after the negative smear. Thus, it is likely that at least some of these patients had precancerous lesions or early cancer at the time of screening. Because Stockholm's laboratories enjoyed an excellent reputation, Rylander's publication should have elicited a major outcry but it did not. These European reports were ignored in the US because the competence of the cytology laboratories was unknown.

However, the review of the American literature from the years 1970-1983 clearly shows that failures of the cervical smears as a case-finding procedure were also recognized in the United

States. Thus, Figge et al (1970), Gunn and Gould (1973), Shulman et al (1974), and Fetherstone (1983) reported that cervical smears failed in recognizing a substantial proportion of precancerous lesions or invasive cancer diagnosed by biopsy. The accuracy of the cervix cancer detection system was questioned by Foltz and Kelsey (1978). Again, these reports were ignored.

However, the issue was brought into sharp focus when an investigative journalist, Walt Bogdanicz, reported in the *Wall Street Journal* on November 2, 1987, that young women were dying of cervix cancer because of laboratory errors. He received a Pulitzer prize for his reporting. Perhaps because of the type of readership that the *Wall Street Journal* enjoys, Bogdanicz's report resulted in a flurry of legislative activity in the Congress of the United States, "to protect the American women from bad laboratories." The resulting legislation, enacted in 1988, is the Amendment to the Clinical Laboratory Improvement Act, known as CLIA 88, which put the performance of the laboratories processing cervicovaginal material under Federal jurisdiction. The practical issues pertaining to laboratory operation, resulting from CLIA 88 are discussed in Chapter 44.

The Bogdanicz report also elicited the interest of attorneys representing women whose injuries (and sometimes death from invasive cancer of the uterine cervix), were allegedly caused by misinterpretation of cervical smears. Subsequently, a flurry of legal proceedings against pathologists and laboratories took place, sometimes with substantial monetary penalties assessed by juries. All these events led to a thorough re-examination of laboratory performance in cervicovaginal cytology, casting new light on the effectiveness of cervicovaginal cytology. **It became rapidly apparent that errors of omission (false-negative smears) and, to a much lesser extent, errors of commission (false-positive smears) occur in virtually every laboratory of cytology,** although the rate of these errors may vary significantly among them. The detection and classification of cytologic abnormalities in cervicovaginal material, whether in the form of direct smears or material prepared from liquid samples, belongs to the most **difficult human tasks**. In an average laboratory, at least 90% of preparations show no findings of note and require no further action. Therefore, only a relatively small proportion of cytologic samples contain abnormal cells that may be few in number, small in size, difficult to interpret or obscured by benign cells, blood, inflammatory exudate or debris. The identification of such cells or cell clusters under screening power of the microscope requires a high level of undivided attention of the screener, which is difficult to maintain over a period of many hours of work. Further, the decision whether the observed abnormalities are of benign or malignant nature may also cause substantial problems.

ERRORS IN THE INTERPRETATION OF CYTOLOGIC SAMPLES

False-Negative Smears

Numerous papers have been published at the end of the 20th century examining the rate and causes of false-negative smears. Only a few key contributions will be analyzed. An important early study by van der Graaf et al (1987) was based on a second review of **prior negative smears** in 555 women (out of a total screened population of 165,185 women) who 3 years later were shown to have biopsy-documented moderate or severe dysplasia, carcinoma in situ or invasive cancer. On review 12.3% of the smears were considered inadequate, 58.3% were found to be "atypical," and **29.3% of the smears contained missed evidence of "dysplasia" or "carcinoma in situ."** The study did not address the issue of the sources of errors, whether caused by **faulty sampling, screening, or interpretation, but it did document that the performance of a reputable laboratory is fraught with considerable error. The manner in which this error is assessed is important.** If the error were to be calculated as a percentage of smears missed in the entire screened population of 165,185 women, it becomes minuscule. If, however, the error is calculated as a proportion of lesions missed, as shown in Table 11-10, it becomes substantial. **The only meaningful way of presenting data on false-negative smears is as a percentage of biopsy-documented abnormalities.**

There were several studies showing that there is a **substantial false-negative rate** (20% to 30%) of cervicovaginal smears in patients with biopsy-documented invasive carcinomas of the uterine cervix (Troncone and Gupta, 1995; Tabbara and Sidawy, 1996; Bergeron et al, 1997; Kok et al, 2000). All these studies documented that approximately three-quarters of the previously negative smears showed, on review, some degree of cytologic abnormality. Relatively few of these false-negative smears showed evidence of HGSIL (20% in the Bergeron study). Most of these **"false-negative" smears showed either evidence of LGSIL or of ASCUS.**

Mitchell and Medley (1995) and O'Sullivan et al (1998) noted that the **small size of cancer cells and their scarcity in smears** are major sources of false-negative smears. Fewer than

200 abnormal cells in a preparation is an important source of diagnostic errors. Montes et al (1999) considered the presence of "atypical metaplastic cells" as the source of diagnostic difficulty in negative smears of women who subsequently developed HGSIL. These cells were discussed above.

P.365

TABLE 11-10 RELATIVE INCIDENCE OF HISTOLOGICALLY CONFIRMED PRECANCEROUS LESIONS OF THE CERVIX IN YOUNG WOMEN IN 8 STUDIES

Author	Year	Population Studied (All patients below the age of 20)	Rate of "Other than Negative" Cytology	Rate of Histologically Confirmed Precancerous Lesions (Dysplasia and Carcinoma in Situ)
Ferguson	1961	2,300	33.4/1,000	14.3/1,000
Kaufman et al.	1970	10,246	29.4/1,000	4.8/1,000
Wallace and Slankard	1973	7,520	6.7/1,000	5.8/1,000
Snyder et al.	1976	27,508	8.9/1,000	2.7/1,000
Fields et al.	1976	33,641	42/1,000	Unknown*
Personal data (Hein et al.)†	1977	403†	35/1,000	3.4/1,000 (mainly LGSIL)
Rader et al.	1997	630	10/1,000 (ASCUS)	5/1,000
Moscicki et al.	2001	605 (496 HPV positive)	Unknown	21/1,000 (LGSIL only in HPV positive women)

* Only a few of 58 patients with cytologic suspicion of a precancerous lesion were referred for diagnosis. Seven dysplasias and four carcinomas in situ were confirmed and treated.

† Girls, ages 12 to 16, mean 15.

An authoritative review, encompassing 312 laboratories of cytology in the United States that volunteered for this survey, was presented by Jones (1995). On rescreening of 3,762 smears in women who developed biopsy-documented high-grade intraepithelial lesions or invasive cancer, about **10% of smears were false-negative. If the diagnoses of ASCUS or AGUS were included as diagnostic mistakes, the error rate rose to about 20%.** An analysis of the sources of errors disclosed several components, such as **adequacy of sampling, accuracy of screening, and adequacy of interpretation.** These will be discussed in sequence.

Adequacy of the Cervical Sample as a Source of False-Negative Results

The definition of an adequate cytologic sample was provided in Chapter 8. Briefly, such material should contain cells **representative of the exo- and endocervix but is age-related.** The interpreters of the Bethesda System, Kurman and Solomon (1994), defined an **adequate smear as a smear with "at least 10% of the slide surface covered by well preserved and visualized squamous cells and at least two clusters of five endocervical cells representing the transformation zone and the endocervical epithelium."** These

minimal criteria are clearly arbitrary and are not applicable to postmenopausal women with atrophy (see Chap. 8). For smears not meeting these minimal criteria, the Bethesda System offers the option of considering the cervical sample as either **unsatisfactory (rejected) or examined and found unsatisfactory** for whatever reason.

Specimen adequacy in liquid preparations is rather poorly defined. Solomon et al (2002) suggested that 5,000 well preserved squamous cells per preparation constitute an adequate liquid sample. The scientific evidence supporting this statement was not cited. The presence of endocervical cells in such preparations, as a criterion of adequacy, was not specifically discussed.

Several papers addressed the issue of **inadequate material** as a source of false negative errors, based on review of earlier "negative" smears in women developing high-grade lesions or carcinoma. Gay et al (1985), van der Graaf et al (1987), Sherman and Kelly (1992), Davey et al (1994), Mitchell and Medley (1995), and Kok et al (2000) observed that **some "false-negative" cervical smears contained no abnormal cells**. The rate of such smears varied from one laboratory to another but the average was about 10% to 12%. Most such smears were considered to be **sampling errors. This is not necessarily correct; adequate samples can also be false negative, apparently because some lesions do not shed abnormal cells**. Richart (1964) estimated that 1.4% of precancerous lesions fall into this category. During the follow-up studies of precursor lesions and reported in detail in Part 1 of the chapter (Koss et al, 1963), some patients with known intraepithelial lesions had interval smears free of abnormal cells (see Fig. 11-22). The reasons for these observations are not clear and may be related to the adhesiveness of the cells within the abnormal epithelium. Rubio and Lagerløf (1975) suggested that energetic douching or cleansing of the cervix prior to sampling may account for some of these events. However, regardless of cause, the absence of abnormal cells in a cytologic preparation **cannot always be blamed on the smear taker**.

Ransdell et al (1997) reported that 16% of sequential patients with "unsatisfactory" smears were shown, on follow-up, to harbor a neoplastic lesion.

Unusual Presentation of Abnormal Cells

Poorly preserved, inadequately fixed or stained material may be the cause of false negative smears. Another, less common, source of error is caused by the excessive zeal of clinicians who remove **fragments of precancerous lesions or invasive cancer** by energetic sampling. These fragments, sometimes true **minibiopsies**, may be very difficult to interpret

P.366

in smears or liquid preparations and are sometimes **ignored or considered to be fragments of benign endocervical or endometrial epithelium**. Lesions composed of medium or small cancer cells are usually the source of such fragments. In most cases, the fragments are accompanied by a scattering of other abnormal cells, occurring singly or in small clusters, leading to the correct diagnosis, but sometimes the single cells are absent and a lesion is missed on screening. In my experience, this occurs more often in postmenopausal women with fragile atrophic epithelial lesions (see above).

Boon et al (1993, 1994) reported the use of a **confocal microscope** to study the thick cell clusters. This costly and difficult-to-use instrument allows the inspection of component cells, layer by layer, and allows recognition of nuclear abnormalities.

Accuracy of Screening

The detection and classification of cytologic abnormalities in cervicovaginal material, whether in the form of direct smears or material prepared from samples collected in a liquid medium, belongs among the most **difficult human tasks**. In an average laboratory, at least 90% of preparations show no findings of note and require no further action. Therefore, only a relatively small proportion of cytologic samples contain abnormal cells that may be few in number, small in size, and obscured by benign cells, blood, inflammatory exudate or debris. The identification of such cells or cell clusters under screening power of the microscope requires a high level of undivided attention of the screener that is difficult to maintain over a period of many hours of work. Further, the decision whether the observed abnormalities are of benign or malignant nature may also cause substantial problems.

Early personal experience with a large population of Planned Parenthood clients, conducted in the 1960s (Melamed et al, 1969), disclosed a first-smear miss rate of about 30% of precursor lesions that were diagnosed on subsequent smears obtained within 6 to 12 months. Because, at that time, the issue of false-negative smears was not urgent, only an aliquot of the original first smears was reviewed. Substantial cytologic abnormalities, missed on screening, were found in nearly all of these smears. The observations were not published.

TABLE 11-11 RESULTS OF PROSPECTIVES RESCREENING OF CERVICOVAGINAL SMEARS FOR 1989-1991

Year	Total of smears	Total rescreened (%)	Total suspicious/positive smears (%)	False-negative (%) *
1989	14,851	2,822 (19)	495 (100)	13 (2.6)
1990	13,837	4,245 (30.7)	532 (100)	19 (3.6)
1991	14,433	3,307 (22.9)	666 (100)	34 (5.1)
Total	43,121	10,374 (24.0)	1,693 (100)	66 (3.9)

* Calculated as percentage of all suspicious/positive smears.

(From Koss LG. Cancer 71:1406-1422, 1993, with permission.)

Several recent studies addressed the question of screening errors. The results of a **second review of smears** of women considered to be at **"high risk"** performed at Montefiore Medical Center is shown in Table 11-11 (Koss, 1993). The procedure is described below. It may be noted that approximately 25% of all smears were reviewed and that, in this population, the **average screening error for the years 1989-1992, as a percentage of abnormal smears, was 3.9%. These errors were prevented by rescreening.** Jones (1995), in a large American study, reported that faulty screening accounted for 74.8% of the errors on 544 smears reported as "negative." Sherman and Kelly (1992), Hatem and Wilbur (1995), and Mitchell and Medley (1995) reported that the **most important common denominator of false-negative smears was the small-cell lesion. Single small cancer cells and dense clusters were most likely to be overlooked or misinterpreted on screening.** This has also been our experience. Other causes of errors leading to false-negative smears are shown in Table 11-12. **Poor recognition of keratinized abnormal squamous cells and underestimation of the significance of clusters of atypical metaplastic cells, sometimes classified as "repair," are of special significance.**

Errors of Interpretation

This issue is rarely addressed in the literature because accurate data are difficult to come by. In the Jones study (1995), **135 of 195 (69.2%) of false-negative smears, initially considered as "benign atypia," were misinterpreted** by the pathologists. Duggan and Brasher (1999) documented that, in 449 cervical smears diagnosed as LGSIL, about 7% were undercalled and 12.5% were overcalled, for an overall 80% accuracy rate for 14 Canadian laboratories. Errors of screening and interpretation accounted for most mistakes. Anecdotal evidence suggests that pathologists, without prior special training and supervised experience in cytopathology of the female genital tract, are most likely to misinterpret the evidence. One of the **essential ingredients** in the interpretation of cervical cytologic material is **time**. The interpretation of a difficult preparation may require 10 or 15 minutes of careful review of the evidence and its analysis, a true

P.367

luxury in the medical climate that requires cost-controlled efficiency on the part of the laboratory personnel.

TABLE 11-12 COMMON SOURCES OF FALSE-NEGATIVE CERVICAL SMEARS

Problem	Solution
Nuclear enlargement in a few intermediate squamous cells (Fig. 12-1).	Either a LGSIL or ASC-US, depending on the number of such cells
Heavily keratinized nucleated squamous cells, regardless of degree of nuclear abnormality	Consider keratinized squamous neoplastic lesion (either in situ or invasive)

Metaplastic cells with nuclear enlargement and nucleoli	Repair reaction, atypical metaplasia, or HGSIL, depending on the severity of the nuclear abnormality and configuration of cell clusters
Endocervical cells with large nuclei and nucleoli	Repair reaction, HGSIL located in endocervical canal, or endocervical neoplasia (see Chap. 12)
Cytolysis with isolated large nuclei	Could be LGSIL with cytolysis; search for well-preserved dyskaryotic cells
Smears obscured by blood or heavy inflammatory exudate	Careful screening is required. Invasive carcinoma must be ruled out
Dense clusters of small or very small cells, mimicking leukocytes	Consider small-cell carcinoma; look for single small cancer cells
Fragments of necrotic tissue in smears; not otherwise interpretable	Consider the possibility of invasive carcinoma; search for abnormal nuclei and nucleoli
Thick clusters of endocervical cells in brush specimens	Could be brush artifact. Search for isolated atypical cells; do not repeat such smears for 3 months
"Pale dyskaryosis"	

SIL, squamous intraepithelial lesion; HG, high grade; LG, low grade; ASC-US, atypia of squamous cells of unknown significance.

False-Positive Cytologic Samples

False-positive cervicovaginal samples are relatively uncommon but may be the cause of considerable anxiety in patients and their caretakers. There are two situations when such events occur: **a sample showing clear evidence of a malignant lesion is not confirmed by biopsies, and misinterpretation of a benign process by the cytopathologists.**

- **Lack of confirmation of a neoplastic lesion by biopsies may have multiple causes,** which were discussed above in reference to correlation of biopsies with cervical samples. The most common cause is **inadequate biopsy** of the uterine cervix. In such cases, the procedure **requires a review of the cytologic sample and of the biopsies, preferably by a second expert observer.** Sometimes the review of the original biopsy material (and recuts) will solve the dilemma because a lesion will be found. If the biopsy review fails to reveal a lesion and **the review of the smear confirms the original opinion, additional sampling of the uterine cervix that may require a conization are indicated.** If, as it sometimes happens, these precautionary common sense procedures fail to reveal a lesion, **further follow-up of the patient by additional cytologic procedures is mandatory. Sometimes, several years of follow-up may be required before the presence of a lesion is documented.** Anderson and Jones (1997) documented patients with abnormal smears and initial lack of confirmation by biopsy require long follow-up to discover occult neoplastic lesions. In some cases, the neoplastic lesions may be located **in the vagina or the endometrium or may even sometimes represent a metastatic cancer.**
- **Removal of the entire lesion by energetic brushings** has been observed, resulting in **biopsies with denuded surface.** Another source of error may be **postmenopausal atrophy** in which the **atrophic lesion** is not recognized or considered to be a "crush artifact" as we have repeatedly observed (see above).
- **True false-positive reports are usually based on misinterpretation of the evidence in the cytologic sample. The most important causes** of such errors are listed in Table 11-13. A second review of such cell samples by a second observer and a correlation with clinical data is mandatory in such cases.

Finally, there is a residue of patients in whom no evidence of disease will be found on long-term follow-up. It is likely that, in such cases, a small focus of disease has been destroyed during the bioptic procedures or that the lesion regressed.

TABLE 11-13 COMMON SOURCES OF FALSE-POSITIVE CERVICAL SMEARS

Findings	Solution
Clusters of endocervical cells with large nuclei and nucleoli	Repair or endocervical neoplasia. Search for single abnormal cells—if present consider neoplasia
Single endocervical cells with large hyperchromatic nuclei, no nucleoli	The patient may be pregnant (Arias-Stella cells) or receiving contraceptive medication with high progesterone content (see Chap. 18)
Ciliated endocervical cell with atypical nuclei	Tubal metaplasia, or rare carcinomas
Atrophic smear with isolated large, dark structures	The so-called “blue bodies” (see Chap. 8)
Atrophic smear with markedly enlarged nuclei in a few squamous cells	Could be atrophy or SIL. Short course of estrogen therapy may solve the problem
Intermediate squamous cells with perinuclear halo, no significant nuclear enlargement	Trichomoniasis (search for parasite) or poorly developed koilocytosis (ASC-US) [search for other evidence of HPV infection]
Multinucleated cells with pyknotic nuclei	Herpes. Search for more classical cell changes (see Chap. 10)
Large squamous cells with cytoplasmic or nuclear vacuoles	Clinical history, radiotherapy, or chemotherapy (see Chap. 18)
Large, dense clusters of endocervical cells with frayed edges	May be brush artifact or endocervical lesion (see Chap. 13)
Clusters of endometrial cells, particularly in brush specimens	May be mistaken for carcinoma. Check menstrual history and estrogen level

SIL, squamous intraepithelial lesion; ASC-US, atypia of squamous cells of unknown origin; HPV, human papillomavirus.

FAILURES OF CERVICAL SAMPLES AS A FOLLOW-UP PROCEDURE

It is customary in many laboratories to suggest that the cervical smear be repeated to confirm a prior ASCUS, AGUS, or “atypical” smear. Studies of patients from Planned Parenthood of New York City conducted from 1967 to 1970 (Melamed et al, 1969) required that a suspicious or positive cervical smear be followed by biopsies or diagnostic conization of the cervix. As a routine procedure, a second smear was obtained just prior to conization. **In approximately 40% of patients with histologically proven carcinoma in situ, the second smear, usually obtained within 3 months or less after the original diagnosis, showed no evidence of abnormal cells.** Similar anecdotal observations were recorded by Nyirjesy (1972), Rylander (1976), and Rubio (1974). Follow-up studies of precursor lesions (Koss et al, 1963) also documented that repeat smears are often negative in the presence of biopsy-documented lesions. A study by Wheelock and Kaminski (1989) also pointed out that at least 40% of “repeat” smears obtained prior to colposcopy failed to reflect the underlying CIN. The issue was studied extensively by Bishop et al (1997) **who pointed out that the sensitivity of repeat cervical smears was low until 120 days have elapsed between smears**, in keeping with prior observations (Koss 1989).

Several important **conclusions of clinical significance** can be reached as a consequence of these observations:

- Follow-up cytologic sampling, within less than 4 months after the original equivocal smear, may result in false-negative smears in a large proportion of patients.
- Short-term follow-up by cytology may be highly misleading; a negative sample, or even two, does not necessarily indicate that the lesion has regressed. A minimum of 3 negative smears over a period of at least 2 years is required before the patient can be assured that she is free of disease.
- The patients should be referred for colposcopy on the strength of the highest cytologic diagnosis, which is often obtained in the first sample.

ATTEMPTS TO IMPROVE THE RESULTS OF SCREENING OF CERVICAL SMEARS

Sampling Instruments

Papanicolaou's early work in cervical cancer detection was based on examination of vaginal pool samples in which the

P.369

evidence of cytologic abnormalities was much diluted. The lesions were discovered because of painstaking and timeconsuming screening and search for single abnormal cells, often hidden among the multitude of benign cells. The instruments currently available for sampling are described in the Appendix to Chapter 8. With the introduction of the cervical spatula and, hence, direct cervical smears by Ayre in 1947, the task of screening became easier because of a greater concentration of abnormal cells in the targeted sample and less contamination with benign cells. It was soon documented that even the cervical smears failed to uncover a certain proportion of precancerous lesions or invasive cancer (see above). Hence, the search began for an ideal sampling device that, with a minimum of screening effort, would provide the most accurate cytologic diagnosis. To improve the sampling procedure, a number of **endocervical brushes and brush instruments, combining sampling of exo- and endocervix, were introduced** (see Fig. 8-45). Several early observers, notably Vooijs et al (1985), Boon et al (1986, 1989), and Deckert et al (1988) provided evidence that, in the presence of endocervical cells secured by brushes, the rate of detection of precancerous lesions of squamous and endocervical type rose. These observations led to a more precise definition of adequacy of the samples, discussed in Chapter 8 and above. However, the use of these instruments is not always totally harmless. Some of the problems that may occur after vigorous brushings are as follows:

- **Energetic brushing** may cause bleeding.
- **Spreading the sticky material** on a slide may be difficult, resulting in thick clusters of endocervical cells that may be difficult to interpret (see Fig. 10-12). Such clusters may have frayed edges and may mimic "feathering," a feature observed in some endocervical adenocarcinomas (see Chap. 12).
- **Repetition of such smears** within a few days or weeks after the original sampling may result in a repair reaction that may also cause problems of interpretation difficult to interpret (see Fig. 10-9). Some of the problems associated with slide preparation and interpretation of brush samples have been solved by placing brushes in liquid fixative for processing (see below).
- **Vigorous sampling** of the upper reaches of the endocervical canal may yield endometrial cells or cells derived from tubal metaplasia that may cause significant difficulties of interpretation (see Chap. 10).

Use of Two Synchronous Smears

Sedlis et al (1974) were the first to study the yield of two cervical smears obtained one after another and independently evaluated on a large cohort of more than 17,000 women. These observers noted that the **failure rate of detection of high-grade lesions was about 25%, either in the first, or in the second set of smears**. Subsequently, several observers, notably Shulman et al (1975), Davis et al (1981), Beilby et al (1982), and others, confirmed that the addition of a second cervical smear increases the yield of cytologic diagnoses of CIN by about 20%. Unfortunately, this relatively simple procedure adds to the costs of screening and, therefore, found little following in the days of managed care. Still, this is an effective screening system, less expensive than liquid-based cell collection.

Second Review of Smears on High-Risk Patients

In 1989, Mr. Paul Elgert, who was then the Chief Cytotechnologist at Montefiore Medical Center, instituted a quality control measure based on **second review of all cervical smears from "high risk" examinees**. For each patient, a computer print-out of past history or current

clinical data were obtained. **Patients referred by clinics for sexually transmitted disease, patients infected with human immunodeficiency virus (HIV), patients with AIDS, and patients with a past history of cytologic or biopsy abnormalities were considered to be "high risk."** All "negative" smears from such patients were reviewed by a second competent observer. The results of a 3-year study, shown in Table 11-11, documented a surprisingly large number of screening errors (3.9% of abnormal smears) that were uncovered by this measure. Because a very high percentage (about 25%) of patients seen at the Montefiore Medical Center fall into the "high risk" category this percentage may be lower in laboratories in different geographic locations. **Nonetheless, the smears from this group of patients contain nearly all of the significant neoplastic lesions. Five-year follow-up of the high risk patients revealed only three biopsy-documented HGSILs that were missed on screening, for an error rate of less than 0.3% of abnormal smears (unpublished data).** The method was adopted by a large laboratory in Paris, France with equally good results (Bergeron and Fagnani, 1995). The cost of the implementation of this technique is the cost of rescreening about 15% of the preparations, somewhat higher than the mandated rescreening rate of 10%. However, **the method is much more efficient at case finding than random selection of preparations for the mandatory quality control.** For further comments on quality control, see Chapter 44.

Five-Year Rescreening

Centers for Disease Control established a set of rules governing cervical cancer screening, discussed in Chapter 44. One provision of these rules, pertinent to this text, is the requirement that all available negative smears, obtained within 5 prior years on patients with biopsy-documented HGSIL or invasive cancer, must be reviewed. Allen et al (1994) identified 44 such patients with 80 smears, of which 14 were reclassified as ASC-US or AGUS (6 cases) and 3 patients in each category as LGSIL, HGSIL. These authors considered the rescreening rule as an effective quality-control measure. Similar experience was reported by Sidawy (1996).

Thirty-Second Rapid Rescreening

This rescreening method was developed in the United Kingdom. The principle of the method is a rapid review of the smear along one horizontal, vertical and diagonal line, the combined review not lasting more than 30 seconds. The initial studies suggested a marked improvement in the recognition

P.370

of abnormal smears and prevention of false-negative results (Baker and Melcher, 1991; Faraker, 1993; Dudding, 1995). Coleman and Evans (1999) considered the results as flawed and suggested that the sensitivity of the rapid review on smears with known abnormalities was between 76% and 80% (Baker et al, 1997). It was noted that, because of the rapidity of the screening process, malignant cells in the track of screening were not recognized, strongly suggesting that **adequate time** is important in the evaluation of cytologic abnormalities.

NEW TECHNIQUES OF CERVIX CANCER DETECTION

As a consequence of legal proceedings following the publication of Bogdanicz's article, numerous commercial companies attempted to improve the yield of the conventional cervicovaginal smear. The principal three approaches to this problem were:

- **Improved methods of cell collection in liquid media and preparation of "monolayer" smears**
- **Automated screening of smears**
- **Testing for human papillomavirus (HPV)**

There is no doubt that the combination of these three new techniques will **reduce the false-negative error rate**, but it can be anticipated that the **number of false-positive alarms and cost to the society will be greatly increased** (recent summaries in Vassilakos et al, 1998; Sherman et al, 1998; Manos et al, 1999; Bishop et al, 2000; Austin, 2003; Limaye et al, 2003).

Liquid Preparations

Starting about 1995, a number of commercial companies introduced systems of cytologic sample collection in a liquid fixative, followed by either **reverse filtration** or **sedimentation**, resulting in a "monolayer" preparation wherein the cells are deposited on the slide within a **small circle**. The staining and screening of these preparations are the same as for direct smears. The details of the techniques are described in Chapter 44. The first system to be approved by the FDA was the ThinPrep method of processing (Cytoc Corp., Boxborough, MA), followed by the AutoCyte Prep; now marketed as SurePath (TriPath Imaging, Burlington, NC). The number of papers on this topic is very large and only a few can be cited here.

The fundamental paper by Lee et al (1997) that was the basis of the approval of the ThinPrep method of processing encompassed 6 laboratories, three within academic hospitals and 3 commercial screening centers. The "split sample" method was used, allowing a comparison between a routine smear and the liquid preparation method. An analysis of the data shows a clear advantage of liquid preparations for the screening centers but little, if any, obvious benefit for the academic laboratories, particularly in the detection of HGSIL or invasive cancer. Ferenczy et al (1996) noted that the ThinPrep preparations had a slightly greater sensitivity and specificity when compared with conventional smears but that the difference was statistically not significant. In marked contrast was the study by Papillo et al (1998) which described an increase in the number of biopsy-documented cases of SIL, particularly LGSIL, with a concomitant reduction in debatable diagnoses. A summary of published data by Austin and Ramzy (1998) also emphasized the diagnostic benefits of the liquid collection systems. Bergeron et al (2001), using AutoCyte Prep reported an increased sensitivity and lowered specificity in patients with high-grade CIN, documented by biopsies. An important study from Costa Rica by Hutchinson et al (1999) documented that the ThinPrep method had heightened the sensitivity but significantly lowered the specificity when compared with conventional smears. These features of this paper were emphasized by Koss (2000). Selvaggi and Guidos (2000) noted that the adequacy of the liquid preparations, not unlike that of conventional smears, depended greatly on the collection instruments and the skills of the provider.

The liquid preparations offer certain advantages and disadvantages. **The most important advantages are:**

- Ease of handling by providers
- Reduction in the proportion of inadequate smears, caused by blood or inflammation
- An increase in the number of cell abnormalities when compared with routine smears; this increase varies markedly from one laboratory to another
- Reduction in screening time, resulting in greater efficiency of the cytotechnologists who can handle a larger number of preparations
- Opportunity to use the residual sample for additional testing, including molecular studies for the presence of infectious agents, such as human papillomavirus (see below)

The disadvantages are:

- Adjustment to modified morphologic images
- Multilayering, resulting in different planes of vision for cell clusters compared with dispersed cells, requiring adjustment of focusing
- Difficulties in the interpretation of dense clusters of cells
- Lowered specificity of diagnoses
- High cost

Klinkhamer et al (2003) reviewed and analyzed the available literature on the AutoCyte Prep, SurePath, and Thin-Prep systems and concluded that the ThinPrep system had a **higher sensitivity** for the detection of squamous precancerous lesions and a **reduced rate of ASC-US**. Similar conclusions were reached by Negri et al (2003). With tissue diagnosis as the end point, Chacho et al (2003) reported occasional failure of the ThinPrep system in the diagnosis of invasive carcinomas. The benefits of liquid cytology are predictably greater for laboratories with a very large volume of cervicovaginal samples than for academic laboratories. **The most important benefit of liquid samples is the option of molecular analysis of the residual material for the presence of human papillomavirus and other infectious organisms.**

P.371

Automated Screening

A number of semi-automated and fully automated devices have been manufactured and some became available for primary screening and quality control rescreening of routine cervical smears in the 1990s. The principles of these devices are discussed in Chapter 46.

The device extensively studied in our laboratories was the **Papnet System**, manufactured by Neuromedical Systems, Inc., Suffern, New York, a company that no longer exists. The device, based on neural net, performed rather well in capturing images of abnormal cells in conventional cervicovaginal smears with resulting decrease in false-negative diagnoses (Koss et al, 1994 and 1997). Several examples of images generated by the Papnet System can be found in this book, particularly in Chapter 24.

An automated image analysis system known as **Focal Point** (previously known as AutoPap, manufactured by Tri-Pathology Imaging, Inc., Burlington, NC) has been approved by the FDA for primary screening of conventional and liquid (SurePath) cervical samples in low-risk women.

Up to 25% of samples designated by the machine as "no further review" need not be rescreened manually. The system has been favorably reviewed by Colgan et al (1997), Bibbo and Howthorne (1999), and Vassilakos et al (2002). A **location guide**, known as Slide Wizzard, has been added to the Focal Point system. It determines the location of abnormal cells on the slide. This system has also received favorable reviews from several investigators (Lee et al, 1998; Chang et al, 2002; Wilbur et al, 2002). The devices are particularly useful in laboratories with a very high volume of cervicovaginal preparations.

HPV Testing as an Adjunct to Cytology

The principles of HPV identification and typing and its role in the genesis of carcinoma of the cervix are discussed at length in Part 1 of the chapter. Briefly, it is assumed that the virus is sexually transmitted, but the evidence supporting this hypothesis is weak because only a small proportion of male partners of women with precursor lesions or invasive cancer harbor the virus and because the same type of virus was very rarely identified in the two partners (Franceschi et al, 2002). The presence of the virus can be documented in a very large proportion of sexually active women. In women below the age of 35 and during normal pregnancy, the rate of **transient infections** documented by polymerase chain reaction (PCR) is very high and may reach 100% in some groups. Although women harboring high risk viruses are at an increased risk of developing precursor lesions or carcinoma of the cervix, epidemiologic data strongly suggest that only a **very small fraction** of these women will develop the disease. There is good evidence that only women with **persisting presence of a high risk virus, documented by two or more tests**, are at risk (Ho et al, 1995; Walboomers et al, 1995; Remmink et al, 1995; Chua and Hjerpe, 1996; Wallin et al, 1999; Nobbenhuis et al, 1999) but, again, they constitute only a small fraction of infected women. In other words, **cervical cancer is a rare complication of infection with oncogenic HPV** (Helmerhorst and Meijer, 2002; Schiffman and Castle, 2003).

An important technologic step in HPV DNA identification and typing was the development of the **Hybrid Capture 2 System** (Digene Corp., Gaithersburg, MD) that is applicable to residual material in liquid samples collected for cytology. The principles of the system are shown in Figure 11-10. Two kits are available, one to detect the presence of low risk HPVs, and the other to detect the presence of high risk viruses. In 2003, the FDA approved the **high-risk kit for testing of patients with ASC-US, regardless of age**, and, in **women age 30 or older** as an **adjunctive screening test** with, or without, a synchronous cell sample. It is the assumption of this approval that the HPV test will offer a **triage option** between women at low or no risk and women deserving further investigation and possibly treatment (see below).

Besides the Hybrid Capture 2 System, other approaches to HPV testing on a large scale are being explored, including several variants of the PCR. **Real time quantitative PCR** appears to be promising (Hubbard, 2003). Undoubtedly, with the passage of time, other testing systems will be developed.

An important development in the history of HPV testing was the **triage study of atypical squamous cells of unknown significance/low-grade squamous intraepithelial lesion (ALTS study)**, sponsored by the National Cancer Institute (Schiffman and Adriaana, 2000). The initial results, pertaining to 642 women with LGSIL, were published in the *Journal of the National Cancer Institute* (2000) as an anonymous paper entitled, "Human papillomavirus testing ... etc." Because 81.4% of the 642 women tested positive for high-risk HPV, it was concluded that the **test offered no triage options and was, therefore, of a very limited value for women with LGSIL**.

In a subsequent publication, Solomon et al (2001) reported on 3,488 women with ASC-US from several participating institutions who were assigned to one of the three arms of the study:

- Immediate colposcopy
- High-risk HPV triage before colposcopy
- Follow-up by cervical smears

The prevalence of HGSIL (CIN 3) in the entire group was 5.1%. The most important conclusion of this paper was that a **negative HPV determination had a very high negative predictive value of about 99%**. In other words, a woman whose genital tract did not harbor documented HPV had a minimal likelihood of developing a HGSIL within the duration of the trial (2 years). On the other hand, although **HPV testing, based on a single initial determination, had a higher sensitivity than cytology, it also had low specificity and high false-positive value, particularly in women below the age of 30**. Stoler and Schiffman (2001) cast yet another shadow on the ALTS study by pointing out that, among the participating institutions, the interobserver **reproducibility of cytologic and histologic diagnoses was low** (kappa value about 0.40, 1 being perfect agreement). Based on the results of the study,

Herbst et al (2001) cautioned that the value of HPV testing should be viewed with caution. Kim et al (2002) calculated that the cost of HPV testing compared favorably with other procedural options, except reclassification of ASC-US as normal.

In a subsequent publication by the ASC-US LSIL Triage Study (ALTS) Group (2003), the cumulative value of CIN 3 in the same group of women was raised to between 8% to 9% and a single HPV test for high risk viruses had predictably higher sensitivity than a single cytologic examination. **After two cytologic examinations, however, the sensitivity of the two tests was equal.** A review by Cuzick (2000) noted that the **specificity** of HPV typing for HGSIL, cancer was **much lower than that of conventional cytology**, resulting in twice the number of women referred for colposcopy. **Clearly, a positive HPV test will stigmatize a great many women who have no documented lesions, all in the name of finding all CIN 3 that could be missed on a single cytologic examination.** As was pointed out above, the **high-grade lesions** discovered in ASC-US patients **are usually small** and not likely to progress to invasive carcinoma (Pinto et al, 2002; Sherman et al, 2003). The issue will be discussed again in reference to follow-up and treatment of ASC-US.

Several possible scenarios of application of HPV DNA analysis have been considered:

- **HPV typing of all women as a replacement for cervical cytology as a screening system for detection of precancerous lesions and early cancer.** Viral typing on a large scale, particularly if performed only once, will select a large proportion of younger women with transient infections who are not at risk for cancer of the uterine cervix. Therefore, this proposal cannot be seriously considered.
 - HPV testing can be used as an ancillary test to cytology in women over the age of 30. The benefits of this approach, approved by the FDA, are not evident as yet. In order to seek out women at high risk of HGSIL, persistence of the oncogenic virus will have to be demonstrated. This would require two or more costly tests at a suitable time interval. Again, women testing positive for HPV in the absence of a documented lesion, will be stigmatized and anxious with untold social consequences.
- Wright et al (2000) promoted the idea of HPV **testing on self obtained samples** from underprivileged women who had no access to cytologic screening. Neither the cost of this enterprise nor access of these women to further care were seriously contemplated. Goldie et al (2001) predictably reported that the effectiveness of HPV testing was higher than direct visual inspection **in the developing countries** but its cost was also higher. These considerations are not applicable to the industrialized societies.
- **HPV typing, as a guide to colposcopy and treatment, only after cytologic evidence of CIN.** The eligibility for colposcopy will be limited to women showing persisting infection with a high-risk HPV type (Nobbenhuis et al, 1999). For a number of reasons discussed in Part 1 of the chapter, this proposal presents a high risk to the patients because of the high failure rate of cytologic screening.
 - **HPV typing of women with equivocal cytologic abnormalities (ASC-US) to identify patients at risk for progression of the lesions** (Sherman et al, 1994; Manos et al, 1999, ALTS studies cited above). The high **negative predictive value** of these studies was documented in the ALTS studies but the **specificity of positive results is questionable.** Some of the published data pertaining to the **specificity of HPV testing** are highly **misleading** because they are based on specificity of the test in the presence of HGSIL. To be sure, nearly all women with biopsy-documented CIN II or III will harbor high risk HPV (Löhrincz and Richart, 2003). However, if the test is applied to a larger population of women of all ages, most of the younger, transient carriers of high-risk HPV will not develop documented disease. Lonky et al (2003) noted a 39.3% false-positive HPV test rate in women with ASC-US. As Löhrincz and Richart (2003) appropriately state, HPV testing offers a **protection against potential litigation.** In the Manos paper, HPV typing compared favorably with the results of follow-up smears, but at a much higher cost. Several newer papers examined the management strategies of ASC-US using the Hybrid Capture System compared with cytology, with generally favorable results (Bergeron et al, 2000; Solomon et al, 2001; Wright et al, 2002; Wright and Schiffman, 2003; Löhrincz and Richart, 2003). Sarode et al (2003) examined the effect of **reflex testing** on all patients with ASC-US, and observed that 91% of HGSIL were HPV positive (2% for low risk viruses). Levi et al (2003) also addressed the issue of **reflex testing** for women with ASC-US, reported that clinicians do not pay much attention to the cytology report and refer patients with positive high risk HPV test to colposcopy.
 - **HPV typing may, perhaps, be of value in the interpretation of biopsies of lesions difficult to classify** (Crum et al, 1997; Park et al, 1999). The results of these interesting studies are not persuasive because of the low specificity of HPV typing.

As discussed in a thoughtful editorial by Crum (1998), with increasing sensitivity of the methods of HPV detection, such as described by Kleter et al (1998), the frequency of positive results also increases, reducing the specificity of the test and confusing still further the value of HPV testing as a public health measure. Wright and Schiffman (2003) also cautioned about the downside of HPV testing.

HPV Vaccines

An apparently successful trial of a human HPV vaccine was reported by Koutsky et al (2002).

Application of HPV Testing to Clinical Practice

A series of recommendations for handling of patients with abnormal cytology were adopted at a National Consensus Conference in Bethesda, MD, in 2001 (Solomon et al, 2002; Wright et al, 2002). These recommendations were formalized as guidelines by the American Society for Colposcopy

P.373

and Cervical Pathology (ASCCP). The society summarized these recommendations in a series of algorithms pertaining to various levels of cytologic abnormality (Cox, 2003). These recommendations that incorporate HPV testing as an important step in the management of patients are summarized in Figure 11-75.

ASC-US (Atypical Smears)

The management options include:

- **Follow-up by smears 6 months later**
- **HPV testing: if negative**—return to routine screening schedule (the screening interval could be extended to 3 years) and **if positive**—refer to colposcopy
- In some laboratories, the HPV testing is “**reflex**” and is automatically performed on any ASC-US cytology results
- **Postmenopausal women with atrophy** may require estrogen therapy before repeat smears or may be referred for colposcopy or HPV testing without delay

ASC-H (Suspicious Smears)

The management options are as follows:

- **Colposcopic examination**
- If no lesion is seen, refer the patient for follow-up, HPV testing and cytology (every 6 to 12 months, possibly followed by **diagnostic conization**)

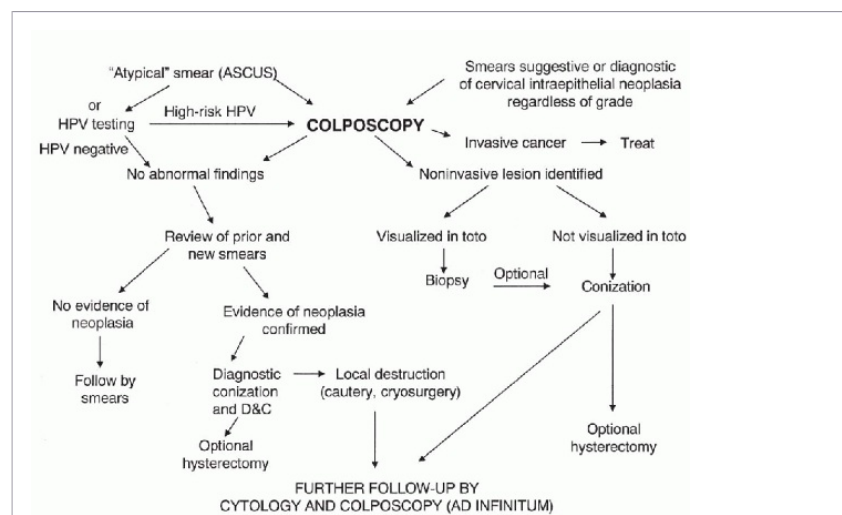

Figure 11-75 Diagnostic and therapeutic choices available to women with abnormal cervical cytology. The sequence of events in this diagram attempts to include all diagnostic and therapeutic options. Colposcopy and biopsies of the cervix remain the pivotal diagnostic procedures, leading to therapeutic decisions. Testing for HPV, which may be “reflex” (i.e., performed on all samples reported as ASC-US) to “selective” (i.e., limited to high-risk patients), is a step added to the list of diagnostic options. Although this approach increases the number of early neoplastic events discovered, its long-term impact on morbidity and mortality from cancer of the cervix remains to be proven.

LGSIL

The management options are as follows:

- **Colposcopic examination**
- HPV testing has been shown to be of no diagnostic or prognostic value
- In **postmenopausal women**, estrogen therapy may be of value before colposcopy
- In **adolescents**, a **conservative (wait and see) approach** may be adopted

HGSIL

- **Colposcopic examination with biopsies**
- If colposcopy is negative and, on review, the cytologic diagnosis is confirmed, a **diagnostic conization** is indicated

BIOPSY CONFIRMATION OF CONCLUSIVE CYTOLOGIC EVIDENCE OF NEOPLASTIC LESIONS

The evidence has been presented in the preceding pages to show that the spectrum of neoplastic events in the uterine cervix comprises lesions ranging from low-grade CIN lesions (LGSIL, mild dysplasia, CIN grade I) to invasive carcinoma. It has been emphasized that the **cytologic presentation**

P.374

may be, at times, misleading and show a pattern of abnormalities that may be much below the level of the histologic abnormality. Therefore, in my judgment and experience, any patient with cytologic abnormalities suggestive, or diagnostic, of a neoplastic lesion of the uterine cervix, regardless of results of HPV testing, should be referred for colposcopic evaluation and for possible biopsies of abnormal areas. This referral must take place on the basis of the first abnormal smear because of the very high failure rate of "confirmatory" smears, as outlined in the preceding paragraphs.

The recommended procedures in handling patients with abnormal smears are shown in Figure 11-75.

It must be stressed that the option of cytologic follow-up, instead of colposcopy for patients with low-grade lesions, is judged to be acceptable because of the high rate of disappearance of these lesions (Kurman et al, 1994). In fact, smears in many women with this disorder will revert to normal (Alanen et al, 1994). **This conservative approach may be used so long as the practitioner and the patient are aware of the caveats pertaining to the failure of smears in the accurate assessment of the lesion and as a follow-up procedure, and the failure of the patients to present themselves for follow-up examination. Clearly, the patient must be informed about the findings and their significance and should consent to the conservative approach after a careful explanation of the options.** Colposcopy and biopsy, followed by conservative treatment of the lesions, are clearly safer for the patient than cytologic follow-up that must be extended for a minimum of 3 years. As discussed above, there is limited evidence that HPV testing is useful in these patients.

COLPOSCOPY AND CERVICOGRAPHY

The **colposcope** is a stereoscopic magnifying instrument allowing an inspection of the uterine cervix at magnifications from 4 to 20 times. The inspection of the cervix is helped by application of a weak solution (2% to 3%) of acetic acid, which dissolves mucus. The instrument also allows the inspection of the remaining areas of the portio and of the adjacent vagina. **The areas of neoplastic epithelial changes, ranging from low-grade lesions (LGSIL, mild dysplasia) to HGSIL or carcinoma in situ, are characterized by vascular abnormalities.** The patterns of the visible vascular changes have received various descriptive terms, such as "mosaic" or "punctuation." The inspection may also reveal **white zones of surface keratinization** or "**leukoplakia**."

Stafl (1981) introduced a variant of colposcopy, **cervicography**, based on color photographs of the cervix obtained with a special apparatus, the cerviscope, and evaluated by an expert.

Patients with abnormalities observed in the photographs are requested to return for colposcopy. Ferris et al (2001) reported that cervicography was of moderate value in detecting high-grade lesions in women with ASC-US or LGSIL. Schneider et al (2002) reported that for neoplastic lesions, the sensitivity of cervicography was 64% and specificity 94%.

Colposcope-Guided Biopsies of Cervix

Experienced colposcopists claim that they can identify varying degrees of epithelial abnormality and early invasion with only a small margin of error. Nevertheless, it is mandatory and prudent to confirm the visual impression by colposcopic biopsies, which have the advantage of being obtained under visual control and, hence, directly from the abnormal epithelium. Colposcopic biopsies are an office procedure, usually not requiring any anesthesia. Occasionally, the colposcopic biopsies are very small and therefore, difficult to handle in the laboratory and sometimes very shallow—a point of some importance if the suspicion of invasive carcinoma cannot be settled in a decisive manner.

Nevertheless, there are circumstances when even the most expert use of the colposcope and of the colposcopic biopsy will not preclude the necessity of additional investigative procedures, such as endocervical curettage or a diagnostic conization.

USE OF SPECIAL PROCEDURES TO INCREASE THE ACCURACY OF BIOPSIES OF THE CERVIX

Schiller's Iodine Test

In the absence of a grossly visible lesion, painting the cervix (or the vagina) with a solution of iodine (Schiller's test) may assist in localizing epithelial abnormalities. Normal squamous epithelium is rich in glycogen, which combines with iodine to form a **mahogany-brown stain**. If there is an epithelial defect from whatever cause, the defect area remains unstained or poorly stained. Schiller's iodine test provides only a very general guidance in the search for areas to be biopsied (see Fig. 11-20). Certain keratinizing cancers of the portio may contain glycogen and stain with iodine. On the other hand, benign abnormalities, such as eversion of the endocervical mucosa or leukoplakia, may fail to stain with iodine. Schiller's test gives no information on the status of the endocervix. Richart (1964) carefully evaluated the Schiller test by means of a colponicroscope and found that about one-quarter of the patients with known carcinoma in situ and nearly one-half of the patients with other forms of cervical intraepithelial neoplasia failed to display significant abnormality with this test. Rubio and Thomassen (1976) confirmed Richart's observations in a study of 87 patients with precancerous intraepithelial lesions and 100 normal women serving as controls. The study, which was carefully controlled, revealed a high percentage of false-positive and false-negative staining. Most important, Schiller's test proved unreliable in detecting or rejecting areas of precancerous abnormalities at the surgical margin of the conization specimen. Thus, Schiller's test can only be considered as **a poor substitute for colposcopy** in the detection of precancerous lesions and should be used as a guide to biopsies only if colposcopy is not available.

Toluidine Blue Stain

Richart (1963) advocated the use of 1% aqueous solution of toluidine blue for delineation of precancerous lesions and

P.375

carcinoma in situ in vivo. The method is as follows: The cervix is cleaned with a mucolytic solution, prepared by adding a 1% solution of acetic acid to a 1 oz. (30-ml) cup, the bottom of which has been covered by Caroid powder. Following cleansing, the cervix is dried with cotton balls. The solution of toluidine is then applied with a cotton-tipped applicator. After several minutes, the excess stain is blotted with cotton. The cervix is then washed again with the 1% acetic acid solution; the nonneoplastic epithelium of the cervix becomes decolorized or contains only a faint residuum of stain, whereas the **areas of neoplasia retain a royal-blue stain**. Inflammatory areas and endocervical columnar epithelium (such as eversions) may retain the stain but stain blue-black.

Because toluidine blue is a nuclear stain, the staining reaction correlated with nuclear density. Accordingly, the intensity of the positive (royal-blue) stain reflected, to some degree, the nuclear density of the underlying lesion and was less intense in low-grade lesions (dysplasia) than in high-grade lesions, including fully developed carcinoma in situ. The test has also been applied to oral lesions (see Chap. 21).

Endocervical Curettage (EEC) and Endometrial Curettage

This procedure allows the sampling (scraping) of the endocervical canal with a small curet without resorting to conization. In my experience, the samples are often fragmented and difficult to interpret, particularly in deciding whether or not an invasion has occurred. **It must be stressed that, occasionally, important tissue evidence of cervical neoplastic events, including invasive cancer, may be found in material from endometrial curettage, which always should be inspected with care.**

Diagnostic Conization

This consists of a surgical removal of a conical segment of cervical tissue with the base

comprising the transformation zone, the adjacent ectocervical tissue, and the apex, extending into the endocervical canal, preferably all the way to the internal os. The procedure, requiring anesthesia, may be carried out by means of a scalpel (cold knife conization), a laser beam, or a cautery loop (LEEP). Diagnostic conization is required when:

- **No lesion is visible on colposcopic examination** in the presence of definitely abnormal cytology; thus, the lesion is presumably located within the endocervical canal, which cannot be inspected by the colposcope.
- **Only a part of the lesion is visible to the colposcopist**, and there is evidence of extension into the endocervical canal, beyond the reach of the colposcope.
- **The original biopsies raise the question of invasion**, which cannot be definitely settled in the material available.
- **The evidence in the original colposcopic biopsies** is not in keeping with the cytologic evidence. For example, if cytology is consistent with a fully developed invasive carcinoma and the colposcopic biopsy shows only a trivial epithelial atypia, conization should be performed.
- **The findings of endocervical curettage**, particularly in reference to the presence of invasive cancer, must be clarified.

Diagnostic conization should not be undertaken lightly because the procedure may result in short- and long-term complications (see below). A very close cooperation between the gynecologist and the pathologist is suggested before deciding on diagnostic conization and its scope. **The cytologic sample may often give a very good indication of the location of the lesion and, thus, may guide the gynecologist as to the manner in which the procedure should be carried out. Thus, a lesion composed only of large squamous dysplastic (dyskaryotic) and keratinized cancer cells is presumably located on the portio of the cervix. In such cases, a relatively shallow conization, encompassing the transformation zone and the squamous epithelium of the vaginal portio of the cervix, but not necessarily the entire endocervical canal, should be carried out. On the other hand, if cytologic evidence suggests a lesion located in the endocervical canal, the conization should reach the internal os but need not include all of the squamous epithelium of the portio.**

Regardless of the type of biopsy, certain common rules should apply. Preparation of the cervix prior to biopsy should be very gentle. Any vigorous scrubbing of the surface of the cervix may result in removal of valuable tissue evidence. The cervix biopsy or biopsies should be obtained preferably in a manner that yields information concerning the geographic distribution and the extent of the lesion. Thus, **if multiple colposcopic biopsies are obtained, each should be preserved in a separate bottle of fixative with precise indication of its site of origin, preferably in form of a diagram.**

TREATMENT OF PRECANCEROUS CERVICAL LESIONS

Until the relatively recent understanding of the natural history of intraepithelial precancerous lesions of the cervix, their relatively slow evolution, and low level of progression to invasive cancers, the standard therapy for these lesions was hysterectomy with a resection of the cuff of the adjacent vagina. In some instances, even radiotherapy was used.

Since the 1970s, the tendency has been to apply more conservative approaches to treatment **once invasive carcinoma has been ruled out.** In the absence of invasion, none of the intraepithelial lesions endangers the life of the patient. All lesions may be treated in a manner most consistent with the well-being of the patient and preferably with preservation of the reproductive functions. The latter is particularly important for women who nowadays may delay childbirth until a later age. The principal modes of therapy in chronological order are:

- Conization, either by scalpel (cold knife) or, more recently, by laser beam
- Cautery
- Cryosurgery
- Laser pulverization
- Large loop electrosurgical excision of the transformation zone (LLETZ)
- **Radiotherapy is not indicated for the treatment of CIN**

All these modes of therapy have the advantage of avoiding hysterectomy, hence, preserving the reproductive function. All of these procedures have certain advantages and disadvantages.

Cold knife conization provides the pathologist with a generous sample of tissues and is the

P.376

most secure way to rule out invasive cancer. Jordan et al (1964) emphasized that the removal of tissue in such cases **must include all of the endocervical canal, including the internal os**, because less extensive procedures are apt to leave behind foci of carcinoma in situ or even invasive carcinoma, a point also emphasized by Ferguson and Demick (1960). Anderson et al (1980) stressed that the extension of neoplastic lesions into endocervical glands in histologic sections may reach 3.8 mm or, occasionally, even more. Thus, accounting for 20% shrinkage of tissue, **the depth of the conization must be about 6 mm**. Burghardt and Holzer (1980) emphasized the need for a careful histologic examination of the conization material by step sections to rule out invasive cancer. Luesley et al (1985) reported on **complications of cold-knife conization** performed on 915 patients—in 13% there was **hemorrhage**, in 17% **stenosis of the endocervical canal**, and in 4% either **infertility or abnormal pregnancy**.

TABLE 11-14 RESULTS OF CONSERVATIVE TREATMENT OF CIN

Authors	Treatment Mode	Total Number of Patients Treated	Failure Rate	Remarks
Benedet et al. (1987)	Various	1,675	5%-7% regardless of grade of CIN	81 lesions recurred: 2 CIN I, 16 CIN II, 63 CIN III
Creasman et al. (1973)	Cryosurgery	75	48.5% after one treatment, 18.7% after 2 treatments	
Levine et al. (1985)	Cryosurgery	279	2.9%-5.7% regardless of grade	After subsequent conization, the failure rate was from 0.7% to 2.7%
Anderson (1982)	Laser vaporization	441	23.6% after 1 treatment, 2% after 2nd treatment	
Hatch et al. (1981)	Cryosurgery	772	Persistence 10%-20%; recurrence 3.2%-3.8%, regardless of grade of CIN	
Chanen et al. (1983)	Coagulation diathermy	1,864	2.7% after single treatment	Cost-effective
Deigen et al. (1986)	Cautery	776	10%-11% after 1 treatment	No anesthesia, cost-effective
Baggish (1986)	Laser excisional conization	120	Not reported	Same results with both methods
	Laser vaporization	100		
Hanau and Bibbo (1997)	LEEP	162 (121 with follow-up)	33% LGSIL	LGSIL most common followed by HGSIL

Neither hysterectomy nor cold-knife conization for precursor lesions guarantee cure.

Kolstad and Klem (1976) reported on 1,122 patients with carcinoma in situ treated by conization. The recurrence rate was 2.3% for carcinoma in situ and 0.9% for unexpectedly discovered small invasive carcinomas. After hysterectomy, there were 1.2% recurrent carcinomas in situ and 2.1% invasive cancers. Bjerre et al (1976) reported treatment failure in 13% of patients treated by conization. Among 186 patients treated by hysterectomy 8 developed invasive cancers. Thus, all patients must have the benefit of follow-up for at least 5 years.

The selected results of treatment of CIN by cautery, cryosurgery, and laser are shown in Table 11-14. It may be noted that a failure of treatment occurred in all of the series, regardless of mode of therapy, ranging from a low of 2.7% to a high of nearly 20% in an early study by Creasman et al (1973). With accumulated experience, the treatment failure rate is probably between 3% and 5%. It is of interest that the treatment failure was independent of the grade of abnormality (where reported) and was just as likely to happen with CIN I as with CIN

P.377

III, supporting the concept that the size and location of the lesion are more important than the morphologic grade of abnormality.

The large loop electrosurgical excision of the transformation zone (LEEP or LLETZ), initially proposed by Cartier of Paris, is based on thin wire loop electrodes of various sizes that can be used to excise the transformation zone and the affected segment of the cervix, with a reasonably good preservation of tissues. Low-voltage electrodiathermy current is used for the excision, which is, at the same time, of diagnostic and therapeutic value. Therapeutic successes in about 95% of patients have been reported (Minucci et al, 1991; Wright et al, 1991; Luesley, 1992). The method is not without problems and cervical stenosis has been reported as a complication of the procedure (Dunn et al, 2004). Sadler et al (2004) noted that LEEP, laser cone procedures were a **risk factor** for preterm delivery. The interpretation of the histologic evidence provided by LLETZ, may also present problems because of tissue destruction (Montz et al, 1993).

Follow-up of Treated Patients

All patients with CIN, regardless of mode of therapy, require follow-up by colposcopy and cytology. Regardless of therapeutic procedure, the healing of the cervix takes a minimum of 6 weeks. During this period, cytologic abnormalities caused by treatment and the healing process may be observed (see Chap. 18). **If the smear, obtained 6 weeks or more after treatment, shows cells with neoplastic changes, these must be considered as evidence of a persisting or recurring lesion.**

The efficacy of a single smear in detecting persisting or recurrent CIN is not particularly high, probably on the order of 25% (23% in Falcone and Ferenczy's experience). Therefore, **at least three sets of post-treatment smears must be obtained to rule out the presence of a lesion.** It must be stressed that the **recurrent lesion may occur in the vagina**, after eradication of the cervical disease.

Testing for high-risk HPV may be useful in this regard. **Patients with persisting presence of a high-risk virus are at risk for recurrent lesions** (Chua and Hjerpe, 1997; Schiffman et al, 2003).

LABORATORY PROCESSING OF CERVICAL BIOPSIES AND CONIZATION SPECIMENS**Cervical Biopsies**

Each biopsy should be processed individually and **embedded "on edge."** Because of the fragility of the epithelial lesions, which may readily become detached from the main part of the specimen, **filtering the fixation fluid is advisable and all fragments of tissues, thus obtained, should be embedded.**

Figure 11-76 Diagram of the method of processing the uterine cervix as devised by Foote and Stewart. The cervix is split horizontally, and each half is cut into a series of numbered blocks. A diagram accompanies the specimen so that an accurate designation of the distribution of carcinoma is possible. (From Foote FW, Stewart FW. Anatomical distribution of intraepithelial epidermoid carcinomas of cervix. *Cancer* 1:431-440, 1948.)

Conization Specimens

The exact geographic designation of the areas involved by a precancerous lesion may be of direct value to the patient. Thus, if the margins of the excised specimen are occupied by tumor, further therapy may be necessary. Unless the entire specimen is investigated, a focus of invasion may be overlooked. Therefore, a **systematic approach to the investigation of all tissue specimens of cervical origin is essential**. The surgeon can be of help in the laboratory processing of cervical cones *by designating a predetermined point, for instance, the 12 o'clock area, by a stitch*.

Method of Foote and Stewart (1949)

This method was used in mapping studies of the precursor lesions of the uterine cervix, illustrated in Figure 11-76 and it has proven to be very useful to this day. After splitting the cervical cone (or the cervix in cervical amputation and hysterectomy specimens) horizontally, the anterior and posterior halves are cut vertically into a series of blocks not thicker than 5 mm. Each block is numbered, marked as to the surface that has to be cut, and put into a separate container. A diagram of the cervix is prepared, indicating the area of origin of each block. A map of the distribution of lesions on the cervix can be created.

PROGRAMS OF CERVIX CANCER DETECTION AND PREVENTION

The epidemiologic factors associated with carcinoma of the uterine cervix were discussed in the opening pages of this chapter. The data pertaining to the events in cancer of the uterine cervix were collected as a consequence of population

P.378

screening based on cervicovaginal smears. The screening systems are either based on voluntary participation of women (so-called **opportunistic screening**), as in the United States, or within the framework of programs organized by state-supported health care systems, as in Iceland, Finland, Sweden, the United Kingdom, and the Netherlands. The state-organized programs usually offer cytologic services to women within defined age groups (for example from 25 to 45), and at defined time intervals (for example, every 3 to 5 years), likely to yield the greatest benefits as determined by epidemiologists (Geirson, 1986; Hakama 1978, 1988). The women are reminded of screening intervals and the results are computerized for analysis. For example, the program in the Netherlands, with screening at 5-year intervals, resulted in **stabilization** but not reduction of cervix cancer (Siemens et al, 2004). Marshall (1965, 1968) documented that if the screening is performed on a regular basis within a closed community, invasive cancer of the cervix can be eliminated. Unfortunately, such ideal conditions do not prevail in larger screening programs, all of which have shown a reduction in the rate of invasive

rates of precursor lesions in a given population.

Discovery Rates in Newly Screened Populations (Prevalence Rates)

occult precancerous lesion or carcinoma of the cervix. **The discovery rate is in reverse ratio**

**TABLE 11-15 CLINICAL INVASIVE SQUAMOUS CARCINOMA OF THE CERVIX:
INCIDENCE IN BRITISH COLUMBIA**

Year	Population in Thousands Over Age 20	Total Cases	Incidence per 100,000
1955	422.9	120	28.4
1960	486.4	96	19.7
1965	543.2	80	14.7
1970	664.4	82	12.3
1975	805.5	70	8.7
1980	912.9	63	6.9
1985	1,063.1	68	6.4
1987	1,085.7	44	4.0

Discovery Rates in Returning Populations (Incidence Rates)

previously thoroughly investigated and found free of lesions of the cervix, has to be reexamined

Duration of Precancerous Lesions Before Onset of Invasive Cancer and Probability of Invasion

By determining the age differences among cohorts of women with various lesions of the uterine cervix, an attempt can be made to determine the approximate duration of the stages in the

development of cancer of the cervix. For example, if the average age of women with a LGSIL is 22 years of age, HGSIL 29 years, and invasive cancer 40, it can be speculated that 7 years are required for a low-grade lesion to "progress" to a high-grade lesion and 11 years are required for a high-grade lesion to progress to invasive cancer. In fact, the issue is much more complex, because the ideal sequence of events is practically never seen. Further, the frequency of precancerous events is vastly in excess of the observed rate of invasive cancer. **Thus, the complex issues of carcinogenesis in the uterine cervix model cannot be explained based on purely epidemiologic data.** Some of the other risk factors, including the role of HPV infection, have been discussed in Part 1 of the chapter.

P.379

Guidelines for Cervix Cancer Detection

The most recent guidelines for detection of precancerous lesions and carcinoma of the uterine cervix, established by a committee of experts, were published by the American Cancer Society in 2002 (Saslow et al, 2002).

- The **start of screening** should be approximately 3 years after the onset of vaginal intercourse but not later than age 21.
- **The screening can be discontinued** at age 70, after three consecutive negative cervical cytology results within a 10-year period.
- **Screening after medical hysterectomy** (with removal of the cervix) **for benign disease** is not recommended. Women with history of CIN II, III should continue screening until three consecutive normal cytology results have been secured over a 10-year period.
- **Screening intervals.** Young women should be screened annually (or every 2 years using liquid-based cytology).

The **frequency** of most effective screening is also being debated. Patients past the age of 30, testing negative for high risk HPV, or patients who had three negative cervical smears may safely be screened every 3 years with a minimal risk of developing cervix cancer (Sawaya et al, 2003).

New Technologies

- **Liquid cytology.** Because of greater sensitivity, a 2-year interval between screening is permissible (*the statement does not address the issue of lower specificity—author's comment*).
- **HPV testing.** The frequency of combined cytology-HPV testing should **NOT** be done more often than 3 years. Counseling of patients about HPV infection is mandatory.

Additional Recommendations

Women should be educated that a pelvic examination is not equal to a Pap smear [*the opposite statement that the Pap smear is not an adequate diagnostic modality in the presence of abnormal clinical findings was not included (author's comment)*].

Appendix—The 2001 Bethesda System

The Bethesda System (The NCI Terminology and Classification of Cervical / Vaginal Cytology). Developed and approved at the National Cancer Institute Workshop on Terminology for Cervical / Vaginal Cytology, December 12-13, 1988; modified 1991 (JAMA, 267:1892, 1992, and 2001) (Solomon et al, 2002).

ORGANIZATION OF THE NEW TERMINOLOGY AND CLASSIFICATION

It is recommended that laboratory reports address each of the following elements:

- **Specimen type** (Pap smear, liquid-based, other)
- **A statement on the adequacy of the specimen** for diagnostic evaluation
- **A general categorization** of the diagnosis (*within normal limits or other*)
- **Descriptive diagnosis**, using the following terminology and classification.

Specimen Adequacy

- Satisfactory for evaluation (note presence/absence of endocervical/transformation zone component)
- Unsatisfactory for evaluation ... (specify reason)

- Specimen rejected/not processed (specify reason)
- Specimen processed and examined, but unsatisfactory for evaluation of epithelial abnormality because of (specify reason)

GENERAL CATEGORIZATION (OPTIONAL)

- Negative for intraepithelial lesion or malignancy
- Epithelial cell abnormality
- Other

INTERPRETATION/RESULTS

- Negative for intraepithelial lesion or malignancy
- Organisms
- *Trichomonas vaginalis*
- Fungal organisms morphologically consistent with *Candida* species
- Shift in flora suggestive of bacterial vaginosis
- Bacteria morphologically consistent with *Actinomyces* species
- *Cellular changes consistent with herpes simplex virus*
- Other non-neoplastic findings (Optional to report; list not comprehensive)
- Reactive cellular changes associated with inflammation (includes typical repair)
- Radiation
- Intrauterine contraceptive device
- Glandular cells status posthysterectomy
- Atrophy

EPITHELIAL CELL ABNORMALITIES

Squamous Cell

- Atypical squamous cells (ASC) of undetermined significance (ASC-US)
- Cannot exclude HSIL (ASC-H)
- Low-grade squamous intraepithelial lesion (LSIL) *encompassing* human papillomavirus/mild dysplasia/cervical intraepithelial neoplasia (CIN) 1

P.380

- High-grade squamous intraepithelial lesion (HSIL) *encompassing* moderate and severe dysplasia, carcinoma in situ; CIN 2 and CIN 3
- Squamous cell carcinoma

Glandular Cell

- Atypical glandular cells (AGC) (specify endocervical, endometrial, or not otherwise specified)
- Atypical glandular cells, favor neoplastic (specify endocervical or not otherwise specified)
- Endocervical adenocarcinoma in situ (AIS)
- Adenocarcinoma
- Other (list not comprehensive)
- Endometrial cells in a woman ≥ 40 years of age

Comment

The key to successful practice of gynecologic cytopathology (and tissue pathology) is excellent communications between the laboratories and the gynecologists or other practitioners interested in their patients. Many a difficult diagnostic problem, in a cytologic sample or in a biopsy, can be resolved by a discussion with the clinician. Bits of valuable information, not included in the brief summary submitted with the laboratory request, may have a major impact on the diagnosis and recommendations in reference to further handling of the patient's problem.

Adenocarcinoma and Related Tumors of the Uterine Cervix

EPIDEMIOLOGY

Adenocarcinomas derived from the endocervical epithelium constitute approximately 10% to 15% of all invasive cancers of the cervix. There is suggestive evidence that the **frequency** of endocervical adenocarcinoma may be **on the rise** (Kjaer and Brinton, 1993). It is possible that a better recognition of this group of lesions combined with a reduction in the rate of invasive squamous cancer may account for some of the increase. The increased frequency may be limited to geographic regions: a marked increase has been observed in Australia, United Kingdom and Norway, whereas none has been observed in Italy (Debate, 1999). In the United States, there is some evidence of increase in young women (Peters et al, 1986; Schwartz and Weiss, 1986; Horowitz et al, 1988). The disease occurs in adult women of all ages but is most common in women in their late 40s or early 50s.

Dallenbach-Hellweg (1981) proposed a possible relationship between endocervical adenocarcinoma and long-term use of oral contraceptives containing progesterone. Peters et al (1986), Jones and Silverberg (1989), Brinton et al (1990), and Ursin et al (1994) found some evidence in support of this concept. Because of a possible association of *all* forms of carcinoma of the cervix with the use of oral contraceptives (see Chap. 10), the selective increase of adenocarcinomas in this group of patients has not been documented in a persuasive fashion. Horowitz et al (1988) and Parazzini et al (1988) failed to observe significant epidemiologic differences between women with squamous carcinoma of the cervix and those with adenocarcinoma of the cervix. In fact, the **coexistence of precancerous squamous lesions or invasive squamous cancer may be observed in nearly one half of patients with endocervical adenocarcinoma, suggesting a common denominator for these lesions**. This common denominator may be **human papillomaviruses, particularly types 16 and 18**, which are frequently observed in endocervical neoplastic lesions (Wilczynski et al, 1988; Tase et al, 1989; Fransworth et al, 1989; Nielson et al, 1990; Duggan et al, 1995; Iwasawa et al, 1996; Riethdorf et al, 2002) (for discussion of the human papillomavirus, see Chap. 11). Endocervical adenocarcinoma may also be synchronous with endometrial cancer (Friedell and McKay, 1953) and with ovarian carcinoma (Livolsi et al, 1983).

P.396

SEQUENCE OF NEOPLASTIC EVENTS

It is generally assumed that the sequence of events in the development of endocervical adenocarcinoma of the uterine cervix is similar to squamous carcinoma, described in the preceding chapter. Theoretically at least, minor morphologic abnormalities of endocervical epithelium, variously termed as “atypia” or “dysplasia,” should precede the development of the

true precursor lesions—the adenocarcinomas in situ—which, in turn, should lead to microinvasive and fully invasive cancers. The term **endocervical carcinoma in situ**, first introduced by Friedell and McKay (1953), has been enshrined in the 2001 Bethesda System of reporting (see Chap. 11). Documenting the sequence of neoplastic events in the endocervix poses problems because, except for its lowest segment, the endocervical canal cannot be visualized by colposcopy and, therefore, cytologic sampling cannot be targeted. Also, in spite of numerous efforts, the morphologic recognition of sequential abnormalities of the endocervical cells is much more difficult than in squamous cells (Lee et al, 2000). The issue is complicated still further by the fact that at least half of endocervical adenocarcinoma is associated with squamous or epidermoid neoplasia in various forms that may have common cytologic features with endocervical neoplasia. To simplify the discussion of a difficult topic, this chapter will begin with a discussion of histology and cytology of invasive endocervical adenocarcinoma, followed by a discussion of precursors.

INVASIVE ENDOCERVICAL ADENOCARCINOMA

Several elaborate systems of classification of endocervical adenocarcinoma have been proposed and recently summarized (Zaino, 2000; Young and Clement, 2002). Because the prognosis of these tumors depends more on stage of disease than histologic presentation (Berek et al, 1984; Kilgore et al, 1988), the simplest classification is their subdivision into common and less common or rare types of tumors.

Among the common types are:

- **Adenocarcinoma mimicking normal endocervical glands**
- **Mucus-producing adenocarcinomas**
- **Endometrioid carcinomas**
- **Poorly differentiated carcinomas**
- **Synchronous adenocarcinoma and squamous carcinoma**

Less common or rare are:

- **Adenosquamous carcinoma**
- **Villoglandular papillary adenocarcinomas**
- **Adenoma malignum (minimal deviation adenocarcinoma)**
- **Glassy-cell carcinoma**
- **Mucoepidermoid carcinomas**
- **Clear-cell carcinoma** (see Chap. 14)
- **Extremely rare adenocarcinomas**

Common Types of Well-Differentiated Adenocarcinoma

Histology

Tumors Mimicking Endocervical Glands

The tumors infiltrate the stroma of the cervix and **form glands similar to normal endocervical glands**, although the glands vary in size and have irregular configuration.

Papillary projections, on the surface of the tumor and within the malignant glands, are fairly common. The malignant glands are lined by one or more layers of tumor cells that are either columnar or cuboidal in shape, have an opaque, granular cytoplasm, and show significantly enlarged, hyperchromatic, coarsely granular nuclei, sometimes provided with large nucleoli (Fig. 12-1A). Histologic diagnosis of the well-differentiated endocervical adenocarcinomas may occasionally cause **diagnostic problems** because the glands may be mistaken for normal endocervical tissue, particularly in scanty biopsies or endocervical curettage material.

A number of **benign variants or benign abnormalities** of the endocervical glands may be mistaken for adenocarcinoma. **Microglandular hyperplasia**, occurring mainly in women with progesterone exposure, **endocervical tunnel clusters**, **mesonephric hyperplasia**, and **endocervicosis** were discussed in Chapter 10. They all have, in common, formation of glandular structures lined by bland benign cuboidal or columnar cells and, regardless of other opinions, are not recognizable in cytologic preparations, contrary to endocervical adenocarcinoma. Thus, cytologic samples may be of significant help in the interpretation of small biopsies of cervix.

A very rare lesion termed **microcystic endocervical adenocarcinoma** mimics benign lesions of the endocervix but the cysts are lined by clearly malignant cells. In some of these patients, malignant cells may be observed in cervical smears but the precise type of lesion cannot be established (Tambouret et al, 2000).

Although many observers consider all adenocarcinomas derived from endocervical glands as mucinous or mucus-producing, it has been my experience that there is little evidence of mucus production in the most common adenocarcinomas wherein it is usually confined to a few scattered cells. Therefore, endocervical adenocarcinomas with a substantial component of mucus-producing cells, are separated out. This subdivision is of value in the interpretation of cytologic findings.

Mucus-Producing Adenocarcinomas

In these tumors, a substantial proportion of cells lining the glands resemble goblet- or intestinal cells, characterized by markedly distended clear cytoplasm filled with mucus (Fig. 12-1B).

Some of these tumors may mimic intestinal cancers because of the presence of occasional **Paneth cells** with cytoplasmic granules. **Signet-ring types** of cancer cells may sometimes occur.

Endometrioid Type of Carcinomas

These tumors form glands lined by one or more cuboidal cancer cells, mimicking a similar tumor of endometrial origin (Fig. 12-1C). Mucus production in the tumor cells is either absent or very limited. The nuclear features of the

P.397

tumors are similar to those of the adenocarcinoma of endocervical type, described above. For a detailed morphologic description of endometrioid carcinomas, see Chap. 13. Some of the endocervical lesions may be traced to foci of endocervical endometriosis. Others probably represent a histologic variant of endocervical adenocarcinoma. In some cases, curettage may be required to determine the origin of the tumor in the endocervix or the endometrium.

Figure 12-1 Examples of histology of endocervical adenocarcinoma. *A.* Tumor mimicking the structure of normal endocervical glands. *B.* Tumor with marked mucin secretions. *C.* Tumor mimicking endometrial carcinoma. *D.* Synchronous presence of a high-grade squamous intraepithelial lesion (HGSIL) and endocervical adenocarcinoma.

As mentioned, **these three dominant tumor types are associated with either precursor lesions (CIN) or invasive squamous carcinomas which occur in about 50% of cases** (Fig. 12-1D). The impact of this association on cytology will be discussed later in this chapter.

Cytology

Cytologic presentation of endocervical adenocarcinoma has been influenced by the widespread use of endocervical brushes. A large number of papers, many cited in this text, described and analyzed the abnormalities of endocervical cells in minute details that allegedly led to a more precise assessment of the sequence of neoplastic events in the endocervix. Following the example of Rosenthal et al (1982), Van Aspert-van Erp et al (1995, 1997), in a series of elaborate studies, analyzed at great length numerous visual and computer-generated features of endocervical cells in **“endocervical columnar cell intraepithelial neoplasia” (ECCIN)**, ranging from mild to moderate to severe atypia, endocervical adenocarcinoma in situ, and invasive adenocarcinoma. When the numerous criteria established in these studies were tested for reproducibility, only a few of them proved to be of practical diagnostic value. They were **essentially the same abnormalities of endocervical cells that have been previously recognized as consistent with adenocarcinoma**. Unfortunately, the analysis of abnormalities of the endocervical cells is further complicated by benign atypias occurring in these cells, discussed in Chapter 10 and later in this chapter. If the endocervical brush-induced sampling artifacts are added to the mix, it becomes evident that the topic of abnormalities of endocervical cells may be extremely complex and the elaborate studies have been of limited value in the practice of cytopathology. ThinPrep liquid preparations of cervical samples have a significant effect on morphology of endocervical cells. **The nuclei are generally smaller (shrunk) and the nucleoli** are often evident in benign cells (Johnson and Rahemtulla, 1999; Selvaggi, 2002).

Cells of Well-Differentiated Invasive Endocervical Adenocarcinoma

It is virtually impossible to separate the three main types of endocervical adenocarcinoma from each other in cytologic preparations, although, occasionally, mucus-producing adenocarcinomas

P.398

may shed cells suggestive of this tumor type (see below). In the cervical material, the **smear background often shows blood, necrosis, and cell debris.**

In samples obtained by either cervical scrapers or endocervical brushes, the following features may be observed:

- The **dominant cancer cells** are usually **columnar**, although often larger or smaller than normal endocervical cells. They have **opaque and granular or clear cytoplasm** and abnormal nuclei. The **nuclear changes** comprise **enlargement, hyperchromasia, coarse granulation of chromatin** and sometimes large, **irregular, and multiple nucleoli** (Figs. 12-2A and 12-3A).
- The cancer cells often form **spherical or oval clusters of superimposed cancer cells**, corresponding to tumor papillae (Figs. 12-2B,C and 12-3B). At the periphery of such clusters, the columnar configuration of the component cells may be observed. On careful focusing, gland formation within the clusters can be observed.
- In yet other cases, **mitotic figures** and **apoptotic break-up of nuclei** may occur (Fig. 12-4A). Occasionally, large malignant cells, without distinguishing features, may be noted (Fig. 12-4B,C).
- The cancer cells are often arranged in **parallel clusters (palisading)**, reflecting the arrangement of the tumor cells on the surface epithelium (Fig. 12-5A).
- They may be **arranged around a central lumen (rosettes)**, reflecting the tendency of the tumor cells to form glands (Fig. 12-5B).
- Approximately spherical “**signet ring**” cancer cells are characteristic of mucus-producing adenocarcinoma. Such cells have a **large, peripheral nucleus** and a **cytoplasm** with a large, **mucus-containing single vacuole or several smaller vacuoles** (Fig. 12-5C).
- **It is not uncommon to observe, in cervical smears of endocervical adenocarcinomas, a few dysplastic (dyskaryotic) or cancer cells of squamous type.** These reflect abortive forms of squamous carcinoma, which maybe associated with endocervical adenocarcinoma (see below). Very rarely, similar findings may be observed in **adenocanthomas of the endometrium** (see Chap. 13).
- **In samples obtained by endocervical brushes,** additional features of such tumors can be noted:
 - **Large, complex clusters of tumor cells** are often removed from the fragile surface of the tumor. Sometimes capillary vessels can be seen coursing through the cluster (Fig. 12-6A). Again, **the search for columnar shape of the component cells and gland formation**

P.399

within the cluster are the essential prerequisites of diagnosis.

- **Isolated “naked” nuclei of malignant cells are more common in brush than in scrape specimens and may be quite numerous** (Fig. 12-6B). Some of these nuclei may appear quite bland and pale (Fig. 12-6C).

- **“Feathering” of cells on the surface of the cluster** is less common, although this feature has been strongly emphasized in the literature. The term, introduced by Ayer et al (1987), pertains to clusters, wherein the peripheral cancer cells are approximately perpendicular to the long axis of the cluster, thus having some resemblance to a feather (Fig. 12-7B,C). It is essential to verify that the **nuclear features of the component cells are those of a malignant tumor because, on rare occasions, this cell arrangement may also occur with benign endocervical cells** and cells from other organs, such as the bronchus (Fig. 12-7D).
- It is of historic interest that, in **adenocarcinoma of the endocervix, the malignant cells will be found primarily in the direct cervical sample, whereas those of endometrial (and tubal or ovarian) origin will be found primarily in the vaginal pool smears** which, nowadays, are unfortunately very rarely obtained. These differences cannot be recognized in liquid preparations.

Figure 12-2 Endocervical adenocarcinoma. A-C. Cancer cells, either dispersed or forming tight papillary clusters. The elongated columnar configuration of some of the cancer cells is particularly evident in A. D. Tissue lesion corresponding to A-C, showing a well-differentiated endocervical adenocarcinoma.

Figure 12-3 Endocervical adenocarcinoma with a different cytologic presentation.

In *A*, the cancer cells mimic normal endocervical cells, except for nuclear enlargement and hyperchromasia. *B* shows a papillary cluster of cancer cells which are much larger than those shown in *A* and shows significant nuclear and nucleolar abnormalities. *C, D*. Tissue sections corresponding to *A* and *B*. In *C*, a clear transition between normal and cancerous endocervical epithelium is shown. *D* shows the invasive component of the tumor.

Poorly Differentiated Endocervical Adenocarcinomas

Histology

These tumors are usually observed in advanced stages of disease as grossly visible tumors of the cervix. Their derivation from either the endocervical or endometrioid adenocarcinomas or, for that matter, poorly differentiated squamous (epidermoid) type of cancer may be difficult to determine. The tumor cells grow in **solid sheets**, wherein only occasional gland formation may be observed (Fig. 12-7).

Cytology

Poorly differentiated adenocarcinomas may be difficult to recognize because of **necrotic debris and blood** that are usually present in such preparations and may obscure cancer cells. The cancer cells derived from such tumors **may retain some of the features of a well-differentiated carcinoma, notably the columnar shape of the cells and the spherical clustering**. In many such cases, however, the cancer cells are **of spherical or irregular configuration, vary in size, and have the characteristic nuclear features of advanced cancer, to wit, irregular shape, coarse chromatin arrangement and large nucleoli**. In some cases, however, **hyperchromasia may be absent and the large nuclei may be pale** (see Fig. 12-6C). The cytoplasm is scanty and, therefore, the **nucleocytoplasmic ratio** is modified in favor of the nucleus. Abnormal mitotic figures may be observed. In such cases, **the diagnosis of cancer is usually evident but the precise cytologic diagnosis of an adenocarcinoma may be difficult to establish and usually requires histologic evidence**.

Figure 12-4 Endocervical adenocarcinoma. *A.* The cluster of cells shows marked mitotic activity. *B.* Scattered cancer cells, some with columnar configuration. *C.* A papillary cluster of poorly differentiated cells with large nuclei and nucleoli. *D.* Tissue section corresponding to *C* showing invasive well-differentiated adenocarcinoma.

Figure 12-5 Endocervical adenocarcinoma. *A.* The smear shows palisading of columnar cancer cells, usually attributed to adenocarcinoma in situ. *B.* Columnar cells forming a rosette (*arrow*). *C.* Signet ring cancer cells. *D.* Tissue section corresponding to *B* and *C* showing invasive mucus-producing adenocarcinoma of the endocervix.

Figure 12-6 Poorly differentiated endocervical adenocarcinoma in a brush specimen. *A.* A large, compact cluster of cancer cells. *B.* Isolated “naked” nuclei of cancer cells. *C.* Cancer cells with bland nuclei forming clusters. *D.* Invasive adenocarcinoma.

Microinvasive Adenocarcinoma

Histology

Using criteria applicable to the definition of microinvasive squamous carcinoma, Christopherson et al (1979) were apparently the first to apply this concept to cervical adenocarcinoma. Tumors infiltrating the cervical stroma to the depth of 5 mm or less were designated as microinvasive endocervical adenocarcinomas. The term was used by Bousfield et al (1980) in a large series of cases without further definition. Betsill and Clark (1986) defined this entity as tumors infiltrating to the depth of 2 mm or less. Mulvany and Östör (1997) described 24 cases classified as microinvasive adenocarcinoma with invasion of 5 mm or less. In such cases, **small malignant glands or solid nests of cancer cells are seen in the cervical stroma, outside of the normal boundaries of the cancerous surface epithelium or glands.** However, as previously discussed, the depth of distribution of normal endocervical glands varies from patient to patient and so do the boundaries. Such tumors virtually never form metastases.

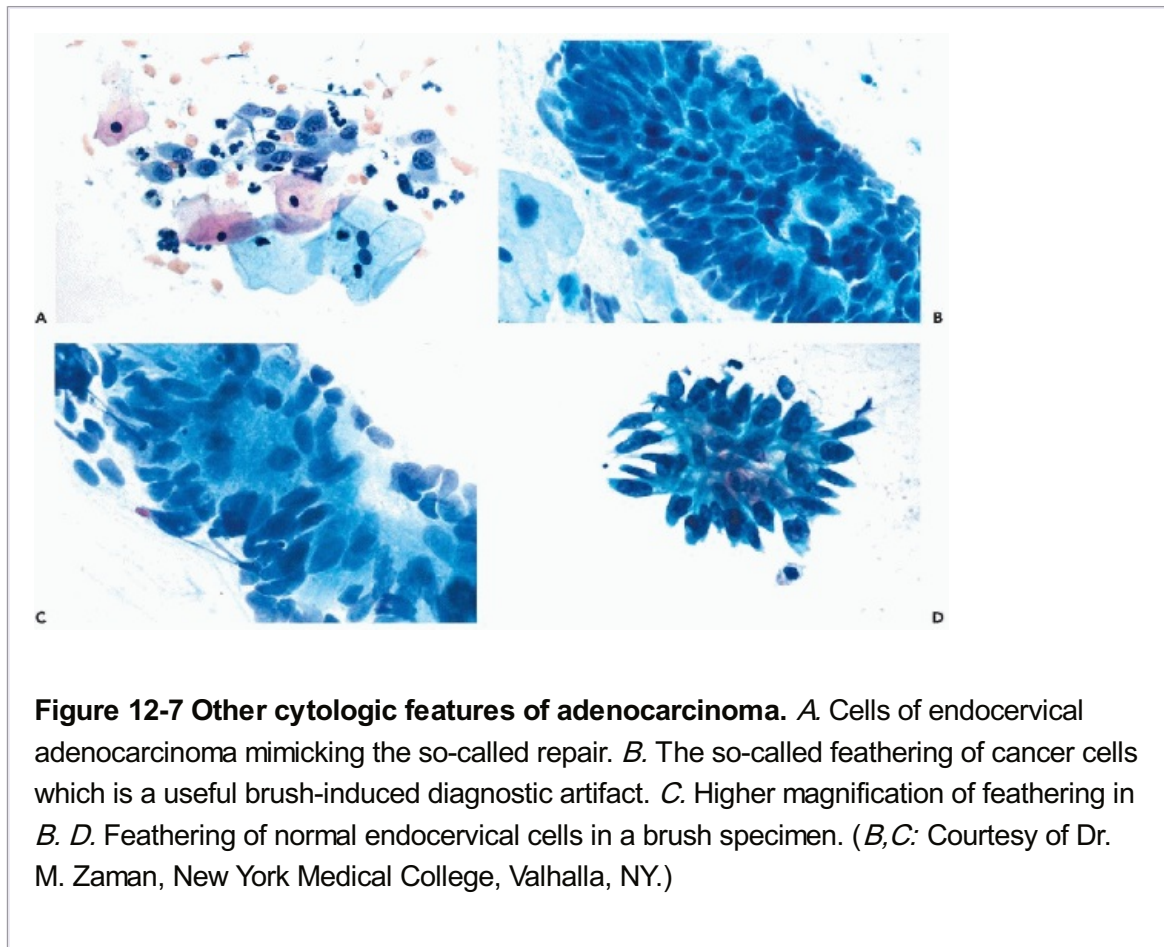

It is our judgment that the diagnosis of **microinvasive endocervical carcinoma is very difficult to establish, is not reproducible, and, in any event, it is of questionable practical value,** because the prognosis of surgically treated endocervical microinvasive adenocarcinoma appears to be as favorable as that of carcinoma in situ, as documented by Betsill and Clark (1986), Östör et al (1997), and Mulvany and Östör (1997).

Cytology

Despite elaborate descriptions by Bousfield et al (1980) and Ayer et al (1988) from the same laboratory, it is doubtful that the cytologic identification of microinvasive carcinoma is possible in a reliable and reproducible fashion. In 12 of the 40 cases so classified, Mulvany and Östör (1997) observed more pleomorphic nuclei, coarse chromatin pattern, karyorrhexis and cell

detritus and, hence, findings consistent with invasive adenocarcinoma described above.

P.402

PRECURSOR LESIONS OF INVASIVE ENDOCERVICAL ADENOCARCINOMA

Endocervical Adenocarcinoma In Situ

It is logical to expect that invasive endocervical adenocarcinomas are preceded by a cancerous change in the endocervical epithelium and glands. By definition, **adenocarcinoma in situ is a malignant transformation of surface and endocervical gland epithelium in its normal anatomic setting.** There are major individual differences in the distribution of endocervical glands and, **in some women, normal glands may be found in the depth of the cervical stroma.** When such deeply seated glands show malignant changes, **it is sometimes difficult to state with certainty whether an adenocarcinoma is still in situ or whether an invasion has taken place.** In most such cases, it is prudent to err on the conservative side.

Histology

The affected **epithelium lining the endocervical canal and the adjacent endocervical glands** is composed of **columnar, less often cuboidal, cancer cells that are usually larger than normal endocervical cells** (Figs. 12-8C,D, 12-9D, 12-10C,D). The size and configuration of the cancer cells is best assessed in cases wherein there is a clear-cut **transition of normal to cancerous epithelium within the same or adjacent glands** (Figs. 12-9D and 12-10D). In some of the glands, “bridges” of cancer cells criss-crossing the lumen may be observed (Fig. 12-9D), as is also the case in other ductal carcinomas such as the

breast (see Chap. 29). The epithelium of some adenocarcinomas in situ contains **Paneth cells** with cytoplasmic granules, suggestive of intestinal differentiation. Although the malignant epithelium may be formed by a **single, fairly orderly layer of cuboidal or columnar cells**, similar to the normal endocervix, **in many areas the cancer cells form two or three layers and short papillary projections**. Nuclear crowding may be particularly evident at the tips of the papillae.

In the cancerous epithelium, the nuclei are enlarged, of irregular contour, hyperchromatic, and sometimes coarsely granular. In some cells, **readily visible nucleoli are present** but this is rarely the dominant feature of these cells. **Mitotic figures are often evident in the cancerous epithelium and are an important diagnostic feature because mitoses are rare in normal endocervical epithelium** (Fig. 12-8D). Biscotti and Hart (1998) pointed out that

P.403

the presence of **apoptotic bodies** (i.e., nuclear necrosis with coarse fragmentation of chromatin; see Chap. 6), within the malignant epithelium, is characteristic of this disorder.

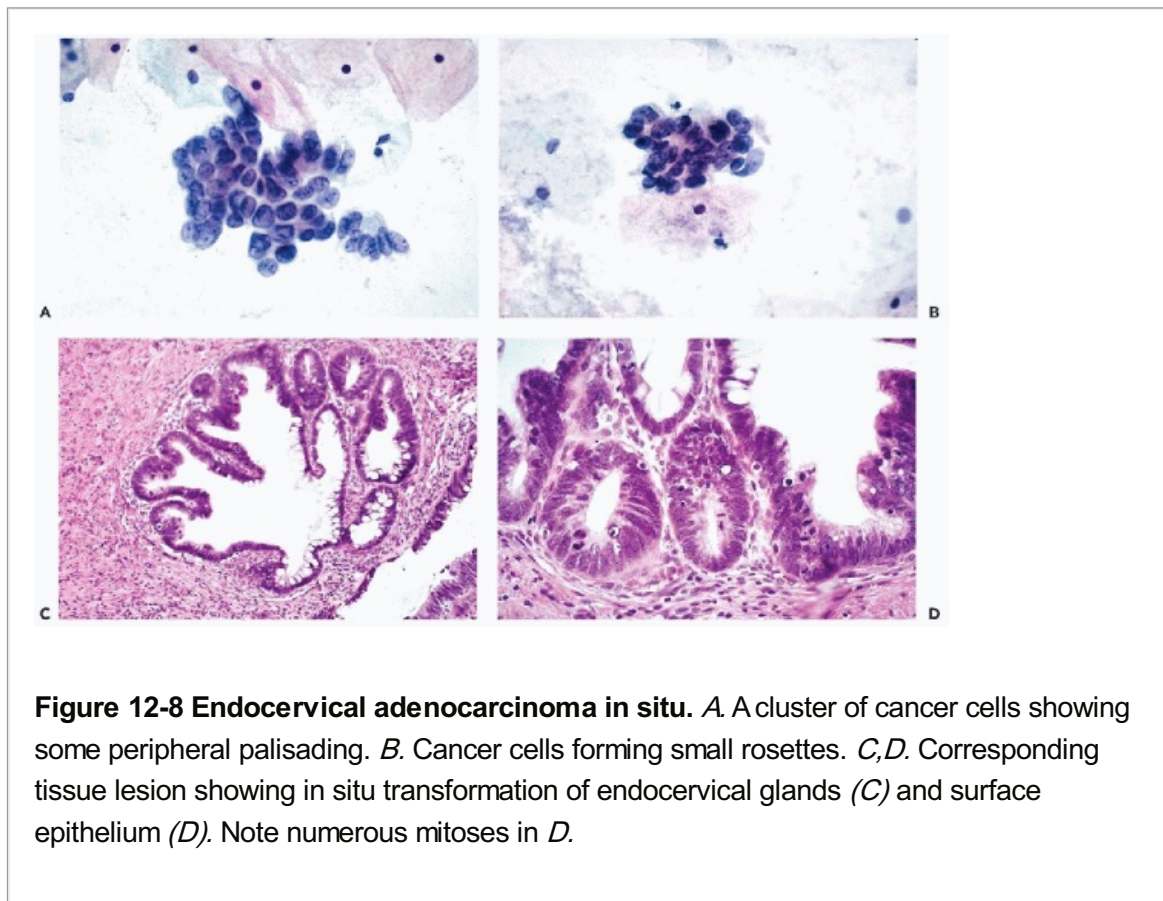

Figure 12-8 Endocervical adenocarcinoma in situ. *A.* A cluster of cancer cells showing some peripheral palisading. *B.* Cancer cells forming small rosettes. *C,D.* Corresponding tissue lesion showing in situ transformation of endocervical glands (*C*) and surface epithelium (*D*). Note numerous mitoses in *D*.

The configuration of carcinoma in situ is similar in nearly all cases, although Jaworski et al (1988) classified two cases as “**endometrioid carcinoma in situ**,” because of absence of mucus production in the lesions. **In a large proportion of cases, endocervical adenocarcinomas in situ are accompanied by preinvasive lesions of squamous type** (CIN) or even invasive squamous carcinoma (see below).

Natural History

There are few reports in the literature about progression of endocervical carcinoma in situ to invasive carcinoma. In the case reported by Büttner and Kyank (1973), 11 years elapsed before

invasive carcinoma developed. Boddington et al (1976) reviewed prior cervical smears in 13 women who developed endocervical adenocarcinoma. In six of these patients, prior cytologic abnormalities were observed over a period of several years, leading to the conclusion that adenocarcinomas have an evolution extending over two to eight years. On retrospective review, Boon et al (1981) observed adenocarcinoma in situ that was not recognized in biopsies obtained three to seven years before the development of invasive adenocarcinoma. Lee and Flynn (2000) estimated that the progression of adenocarcinoma in situ to invasive cancer requires approximately 5 years.

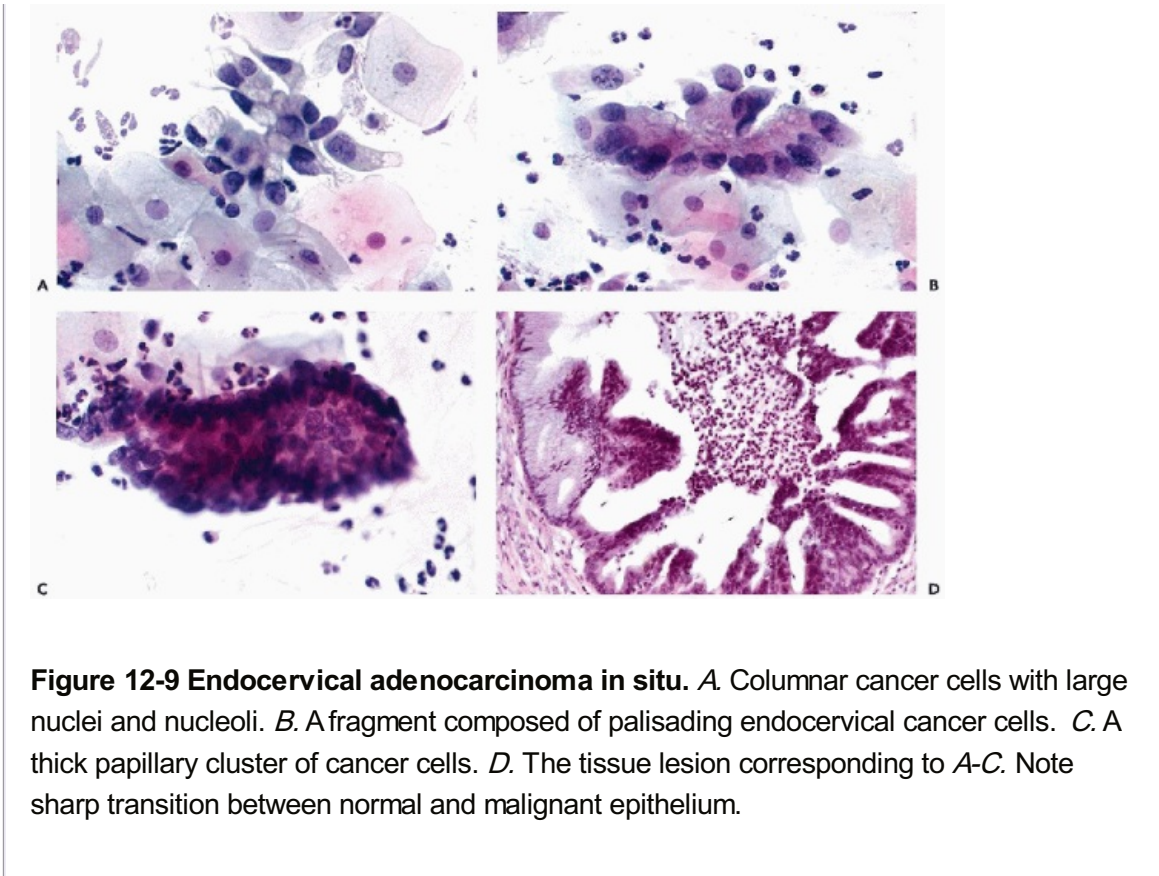

Personal observations also point to a long developmental period in the natural history of these lesions. This information is anecdotal, based generally on cases in which a cytologic diagnosis of adenocarcinoma was followed by **endocervical curettage in which evidence of adenocarcinoma was not recognized**, some years prior to the development of invasive tumor. The most **common source of biopsy error was the presence of strips of mucus-forming epithelium which, in spite of nuclear abnormalities, were thought to represent benign endocervical epithelium** (see Fig. 12-11). Because of the life-threatening nature of endocervical adenocarcinoma, no follow-up studies of untreated adenocarcinoma in situ have been conducted and none should be contemplated. However, in follow-up studies of several personally observed patients treated for adenocarcinoma in situ by conization, it was noted that these patients were prone to the development of other neoplastic events in the cervix in the form of recurrent adenocarcinoma or squamous precursor lesions (CIN).

Cytology

Adenocarcinoma in situ of the cervix has been recognized in the Bethesda System 2001 as a separate cytologic category.

P.404

The cytologic presentation of this entity has been extensively discussed in the literature (Qizilbash, 1975; Betsill and Clark, 1986; Ayer et al, 1987, 1988; Lee et al, 1991, 1997; Keyhani-Rofagha et al, 1995; Biscotti et al, 1997; Cangiarella and Chhieng, 2003; Chhieng and Cangiarella, 2003). In some of the pertinent papers, the smear patterns of this lesion have been compared, on the one hand, with invasive adenocarcinoma and, on the other hand, with benign abnormalities of endocervical cells. The difficulties of cytologic diagnosis of adenocarcinoma in situ have been previously emphasized (Boon et al, 1981; Luesley et al, 1987; Di Tomasso et al, 1996; Lee et al, 1997). Renshaw et al (2004), in an elaborate study of performance of practicing pathologists, reported that the cytologic recognition of this entity was significantly lower than that of other important precancerous lesions or cancer. It is quite evident that there is no unanimity on the reproducible features of this lesion and, therefore, this description is based mainly on personal experience.

The cytologic presentation of an endocervical adenocarcinoma in situ is that of a well-differentiated invasive endocervical adenocarcinoma with several added features:

- The background of the cytologic preparation is usually free of necrosis and cell debris, although a few leukocytes and blood may be present. In our experience, this feature is valuable in separating an adenocarcinoma in situ from invasive cancer (see Figs. 12-8A,B and 12-10A).
- In some cases, fairly slender, dispersed columnar cells with nuclear enlargement and moderate hyperchromasia may be observed (see Figs. 12-8A, 12-9A, 12-10A). Such cells are less common in invasive adenocarcinoma.
- The nuclear abnormalities observed in the columnar or cuboidal malignant cells vary and are sometimes less marked than in invasive cancer: although the nuclei are enlarged and hyperchromatic, they do not always display coarse granulation of chromatin. Large, prominent nucleoli are uncommon (see Figs. 12-8A,B and 12-9A).
- Compact, spherical clusters of malignant cells and fragments of abnormal endocervical glands are fairly frequent (see Figs. 12-9C and 12-10B).
- Cell palisading and “rosette” formation are fairly common (see Figs. 12-8B and 12-9B). These features occur more often in adenocarcinoma in situ than in invasive cancer.
- Signet ring cells and “naked” enlarged and hyperchromatic nuclei are rare. We have not observed the “apoptotic bodies” reported in tissue sections.

P.405

- Changes observed in brush specimens are rarely of value in separating adenocarcinoma in situ from invasive cancer. Large, complex clusters of endocervical cells and “feathering” are observed in both types of lesions, but also

as a brushing artifact with benign endocervical cells (see Fig. 12-7).

- **Occasionally, ciliated abnormal cells may be present.** Although such cells occur mainly in **tubal metaplasia**, discussed in Chapter 10, **their presence does not necessarily indicate a benign lesion** if the nuclear features of such cells suggests a malignant transformation. Endocervical adenocarcinomas with ciliated cells have been described (Schlesinger and Silverberg, 1999).

Figure 12-10 Endocervical adenocarcinoma in situ. *A.* The dominant cells are columnar cancer cells with somewhat enlarged hyperchromatic nuclei. *B.* A small papillary cluster of endocervical cancer cells. *C,D.* Tissue sections corresponding to *A* and *B* and showing the contrast between normal and cancerous endocervical glands.

A number of observers (Bousfield et al, 1980; Betsill and Clark, 1986; Ayer et al, 1987; Pacey et al, 1988; Lavery et al, 1988; Di Tomasso et al, 1996) attempted to classify endocervical adenocarcinomas in situ into well-differentiated and poorly differentiated types, based on the level of nuclear abnormality. In our experience, this subclassification is not reproducible and is not of clinical significance since it does not lead to different prognostic or therapeutic conclusions. **In general, the cytologic diagnosis of an adenocarcinoma is usually fairly easy, but the determination whether the lesion is still in situ or invasive is much more difficult.** The custom in our departments is to emphasize that **the lesion is “possibly” or “probably” a carcinoma in situ.** Bai et al (2000) claimed that the yield of glandular lesions of the endocervix was increased using the ThinPrep technique but this issue is contentious (Cangiarella and Chhieng, 2003).

Endocervical Gland Atypia or Dysplasia

Based on experience with squamous lesions of the uterine cervix, it has been postulated that endocervical adenocarcinoma in situ is preceded by lesser degrees of abnormality that may, perhaps, be recognized in cytologic and histologic samples of the uterine cervix.

The term **endocervical dysplasia** was introduced by Alva and Lauchlan (1975), who

described slight histologic abnormalities of endocervical epithelium that may have preceded an adenocarcinoma in situ. Bousfield et al (1980) used this term to describe cytologic findings not supported by histologic observations although, in two of the three such cases, the initial cytologic diagnosis was adenocarcinoma, not confirmed on biopsy. Brown and Wells (1986), in a review of histology, proposed the term **possibly pre-malignant cervical glandular atypia**, describing changes in endocervical glands accompanying high grade squamous lesions, as shown in Figure 12-3. Wakefield and Wells (1985)

P.406

observed, in such glands, **changes in the composition of endocervical mucus** with increase in sialomucins, similar to those observed in colonic adenocarcinoma. The change can be demonstrated by staining the cells with Alcian blue (pH 2.5) which is negative with normal mucins but positive in the presence of sialomucins. Lee et al (2000) attempted to identify the “dysplastic” lesions with HPV testing and proliferation index with debatable results. In a recent review, Young (2002) qualified these abnormalities as “nebulous” and this writer agrees.

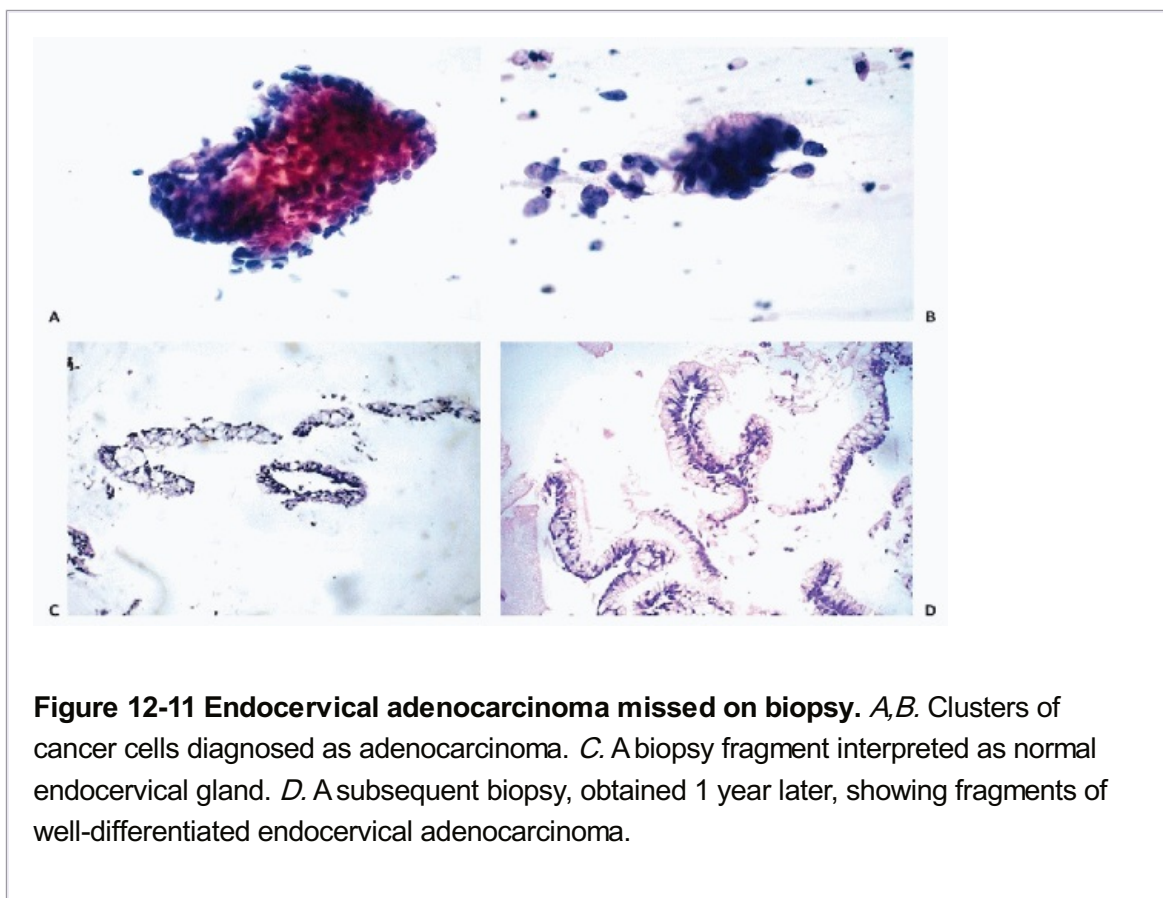

Figure 12-11 Endocervical adenocarcinoma missed on biopsy. *A,B.* Clusters of cancer cells diagnosed as adenocarcinoma. *C.* A biopsy fragment interpreted as normal endocervical gland. *D.* A subsequent biopsy, obtained 1 year later, showing fragments of well-differentiated endocervical adenocarcinoma.

Relatively minor abnormalities of cells lining the endocervical glands may be observed, usually at the **periphery of adenocarcinoma in situ**, or sometimes in **glands adjacent to high grade squamous lesions** (see Fig. 11-35D). **Slight nuclear enlargement and hyperchromasia, sometimes accompanied by irregularly shaped or angular nuclei**, are a common feature of such glands. **Mitoses** may be occasionally observed. Such changes in endocervical cells are **not specific** as they may also occur in a variety of benign events (described in Chap. 10).

Ioffe et al (2003) proposed three criteria to separate “glandular dysplasia” from either benign or clearly malignant noninvasive glandular lesions. These were: nuclear atypia, stratification of cells and the sum of mitosing and apoptotic cells in selected glands. By scoring these three

parameters on a scale from 1 to 3 and adding the results, it was proposed that values 0 to 3 represented a benign lesion, scores 4 to 5 glandular dysplasia, and scores 6 to 9 an adenocarcinoma in situ. The **scoring system** was tested by the authors who reported a good agreement among observers. The value of this proposal must be independently tested.

Because most of these lesions are excised by biopsy, there are no follow-up studies known to us that could clarify the prospective significance of such lesions which we prefer to classify as **“nonspecific atypias of endocervical epithelium”** or glands. Occasionally, such changes are observed **in incidental biopsies of the endocervix** and may sometimes cause diagnostic problems, requiring additional biopsies to determine whether or not the lesion is malignant or, perhaps, adjacent to an adenocarcinoma or even a high grade squamous lesion. In **some of these patients, a squamous lesion or an endocervical adenocarcinoma is ultimately recognized**. The term **dysplasia**, applied to these changes, is not helpful because it does not provide therapeutic guidelines to the clinician. The reproducibility of these diagnoses is doubtful. Lee and Crum et al (2000), using proliferative index and HPV testing, concluded that most of these minor atypias are not precursors of carcinoma.

The 1988 Bethesda System initially recognized the difficulty

P.407

to classify abnormalities of endocervical cells as **atypical glandular cells of unknown significance (AGUS)**. The term has been abolished in the 2001 Bethesda System because of a very large proportion of neoplastic lesions of the uterine cervix that were recognized on colposcopy and biopsies of the cervix (Jackson et al, 1996; Korn et al, 1998; Chhieng et al, 2000; Reuss et al, 2001; Meath et al, 2002; Hammoud et al, 2002). As discussed in Chapter 11, perhaps the most surprising outcome of the AGUS smears was **the high frequency of high-grade squamous intraepithelial lesions (HGSIL) discovered in these women, whereas adenocarcinomas were relatively uncommon**, constituting less than 10% of the lesions found in biopsies of the cervix. An effort to subdivide AGUS into “favor reactive” or “favor neoplastic” was of limited value (Siziopikou et al, 1997; Moriarty and Wilbur, 2003; Cangiarella and Chhieng, 2003). Raab et al (1998) noted that the reproducibility of the AGUS category of diagnoses was very poor among experienced cytopathologists. This was amply confirmed on a more recent study by Simsir et al (2003). As emphasized in Chapter 11, **high grade squamous lesions, located in the endocervical canal, often shed columnar cancer cells, similar to those seen in endocervical carcinomas**.

Cytology

In my experience, there are no specific cell features that would reproducibly identify the atypical endocervical glands, as predictive of an adenocarcinoma. However, it appears appropriate to describe here the nonspecific changes that may be observed in cytologic material.

Atypia of Endocervical Cells

Such abnormalities may be observed in scrape smears and in endocervical brush specimens. The minimal abnormalities in the endocervical cells of potential diagnostic significance are **nuclear enlargement and hyperchromasia of various degrees in otherwise well-formed, but often enlarged columnar endocervical cells**, occurring either singly or in small cohesive clusters (Fig. 12-12A-C). **Coarse granulation of chromatin and irregular nuclear contour are occasionally observed, but nucleoli are absent or small.** Some of these clusters may

show parallel arrangement or **palisading** of endocervical cells, when derived from the surface epithelium (Fig. 12-12C). Such cells were described in Chapter 11 as karyomegaly or dyskaryosis (dysplasia) of endocervical cells but may also occur in cervicitis with negative follow-up (Fig. 12-12D). It is presumed that karyomegaly of endocervical cells corresponds to the term of “**endocervical-columnar cell dysplasia**” (Bousfield et al, 1980) or “**endocervical columnar cell intraepithelial neoplasia of mild or moderate grade,**” a term coined by van Aspert-van Erp et al (1995).

Some of these abnormalities may be classified as **atypical endocervical cells**, discussed in Chapter 11 and above. Their **diagnostic significance is not always clear, because such cell changes represent a common denominator of a broad spectrum of lesions, some of which are benign and some malignant** (Selvaggi and Haefner, 1997). However, the malignant lesions can be **an adenocarcinoma, a squamous precursor lesion of endocervical derivation, or both**. In an occasional biopsy, it is possible to trace the origin of such cells to **atypical epithelium in endocervical glands**, usually adjacent to the transformation zone and commonly observed in high grade squamous epithelial lesions (see Fig. 12-12D and Chap. 10).

Among the benign lesions, it must be noted that **similar and usually transient abnormalities of endocervical cells may occur:**

- **In “repair,” or in florid metaplasia of the endocervical epithelium** (see Chap. 10)
- **In single endocervical cells for a variety of reasons, such as tubal metaplasia or inflammation**
- **During normal pregnancy**
- **In women wearing intrauterine contraceptive devices (IUDs)** (see Chap. 10)
- **In women receiving contraceptive medication with a high progesterone content** (see Chap. 10)

The finding of endocervical cell dyskaryosis, not otherwise accompanied by more conspicuous cell changes, is relatively uncommon, but it is **deserving of a most careful clinical examination, combined with colposcopy, endocervical biopsies or curettage** to rule out incipient carcinoma.

Attempts to Separate Preneoplastic From Nonneoplastic Abnormalities of Endocervical Cells

Because of **limits of morphology** in predicting the future behavior of endocervical cell atypias, several attempts have been proposed to identify women at risk. The chief approach was based on HPV testing, discussed at some length in Chapter 11. Perhaps the most important study cited was the **ALTS study** (Solomon et al, 2001) which documented a **very high negative predictive value** of HPV testing, i.e., extremely low probability that women testing negative for HPV will develop a neoplastic lesion of the cervix. The study failed to demonstrate that the presence of HPV did necessarily lead to neoplastic events. On the other hand, Ronnett et al (1999) reported that testing for high risk HPV types in women with the diagnosis of AGUS **accurately identified the carriers of HGSIL and endocervical adenocarcinoma**. Riethdorf et al (2002) and Negri et al (2003) used the **cyclin-dependent kinase inhibitor (a tumor suppressor gene) p16^{INK4A}** as a marker for HPV-encoded transcription of E6 and E7 open reading frames. The stain was negative or weakly positive in a

number of benign controls and strongly positive in adenocarcinoma in situ. A number of caveats about the specificity of the reaction and its applicability to cytologic samples robbed this observation of practical value. Still, Negri et al (2003) reported **strong expression of this gene in neoplastic endocervical cells** in liquid samples.

Several authors used the **antibody MIB 1** directed against the **proliferation antigen Ki-67**, a marker for mitotically active cells, to separate benign changes from endocervical neoplasia (McCluggage et al, 1995; Cina et al, 1997; Lee et al, 2000; Pirog et al, 2001). The results were equivocal. Lesions with fewer than 10% nuclei staining were usually

P.408

benign and lesions with over 50% of positive nuclei were usually malignant. HPV testing of the lesions with over 10% positive nuclei allowed additional triage of the lesions. The method appears to be effective on both low and high ends of the spectrum but is insecure in cases of microglandular hyperplasia, tubal metaplasia, and in patients with recent biopsies (Lin et al, 2000; Pirog et al, 2001).

Figure 12-12 Examples of atypical endocervical cells, some of which may be the precursor lesions of endocervical adenocarcinoma. *A.* Two clusters of endocervical cells with enlarged hyperchromatic nuclei compared with normal endocervical cells in the same field (*arrow*). The follow-up of this patient was negative. *B.* A cluster of endocervical cells with markedly enlarged, somewhat hyperchromatic nuclei. The follow-up on this patient was negative. *C.* A cluster of palisading endocervical cells with slight nuclear enlargement. The follow-up on this patient was negative. *D.* Biopsy of endocervix corresponding to *C* shows surface epithelium with enlarged dark nuclei. There was no evidence of carcinoma in this case.

Biscotti and Hart (1998) and Moritani et al (2002) observed that **mitotic index** and the presence of **cells showing apoptosis** were characteristic of malignant glandular lesions and

were helpful in separating them from a broad spectrum of benign disorders. Unfortunately, mitoses and apoptosis may not be evident in the cytologic samples and are, therefore, of limited practical value.

SYNCHRONOUS ADENOCARCINOMA AND SQUAMOUS CARCINOMA

Synchronous association of squamous (epidermoid) and adenocarcinoma is a common event that occurs in about half of the glandular lesions (Ayer et al, 1987). Both lesions may be in situ, one of them may be in situ and the other invasive, or both of them may be invasive. Each tumor appears to be leading an independent existence and maintains its behavior pattern, with the adenocarcinoma apparently capable of earlier distant metastases than epidermoid carcinoma. As has been mentioned in the introductory remarks to this chapter, the two types of lesions may have a common denominator in the form of human papillomavirus infection, mainly types 16 and 18.

P.409

Figure 12-13 Coexisting squamous and adenocarcinoma. *A* A cluster of dysplastic squamous cells. *B* Endocervical cancer cells arranged in a form of a palisade. *C* The HGSIL coexisting with endocervical adenocarcinoma shown in *D*. Both lesions were focally invasive.

Cytology

The coexisting adenocarcinomas and squamous carcinomas may shed cells of both tumor types side by side. In many instances, however, the squamous malignant cells conceal or precede the presence of adenocarcinoma. In several personally observed cases, the disease began as a dyskaryosis (dysplasia) of superficial squamous cells, followed without treatment, and culminated in the development of squamous and adenocarcinoma several years later (Fig. 12-13). In many instances, the adenocarcinoma will be a surprise diagnosis in biopsies (Fig. 12-14).

BEHAVIOR AND PROGNOSIS OF THE COMMON TYPES OF ENDOCERVICAL ADENOCARCINOMA

Adenocarcinomas originating within the endocervical canal **may remain clinically occult for long periods of time, unless detected by a cytologic sample or an incidental biopsy.**

Fully developed invasive adenocarcinomas are sometimes bulky and may produce clinical symptoms of spotting, bleeding, or discharge. The tumors rarely occur before the age of 30, but otherwise can occur at any age, most often between the ages of 50 to 60. The **prognosis** of endocervical adenocarcinoma is **stage dependent** (Berek et al, 1984; Kilgore et al, 1988). For staging of cervical carcinomas, see Table 11-3.

For stage 0 tumors (carcinoma in situ and microinvasive carcinomas), the survival after surgical treatment is close to 100%. **Cure of endocervical adenocarcinoma in situ** can be achieved with cold knife conization procedure or a large electron loop excision (LLETZ procedure) but, in many instances, this treatment will be followed by a hysterectomy (Betrand et al, 1987). Hopkins et al (1988) suggested that all these patients should be treated by hysterectomy and lymph node evaluation. Personal experience suggests that women treated conservatively for early stage disease are prone to develop new neoplastic lesions of the cervix with the passage of time and, therefore, should be carefully followed.

For higher stage lesions, the 5-year survival depends on tumor size, grade of differentiation, and depth of invasions (Berek et al, 1984; Kilgore et al, 1988). For high-stage, high-grade lesions, particularly those with spread beyond the uterine cervix, the survival is low. The behavior of the advanced adenocarcinomas is often much more aggressive than that of epidermoid carcinoma of similar stage, and distant metastases may be observed at the time of the initial clinical diagnosis (Saigo et al, 1986; Weiss and Lucas, 1986; Kilgore et al, 1988; Drescher et al, 1989). On the other

P.410

hand, Grigsby et al (1988) reported equal survival for both tumor types in their series of cases.

Figure 12-14 An example of adenocarcinoma which, in the smear, was obscured by the pattern of a high grade squamous lesion. *A,B.* Cancer cells of squamous type. *C.* Fragment of HGSIL. *D.* Underlying endocervical adenocarcinoma.

LESS COMMON TYPES OF ENDOCERVICAL ADENOCARCINOMA

Adenosquamous Carcinoma

These uncommon tumors combine the elements of adenocarcinoma and squamous carcinoma with varying degrees of differentiation (Fig. 12-15A,B). We have seen patients in whom the two patterns were individually represented in separate metastatic foci (Fig. 12-15C,D). The prognosis of these tumors is apparently less favorable than that of classical types of well-differentiated carcinomas (Fu et al, 1982; Gallup et al, 1985).

The cytology of these tumors is identical to that of coexisting adenocarcinoma and squamous carcinoma, described above and shown in Figures 12-13 and 12-14. Either squamous to adenocarcinoma patterns, or a combination of both, may be found in cytologic samples.

Papillary Villoglandular Carcinomas

This relatively uncommon form of endocervical adenocarcinoma has been recognized mainly in women under 40 years of age (Young and Scully, 1989; Jones et al, 1993). Similar tumors may have been reported as “**villous adenoma**” of the cervix with an invasive component (Alvaro and Nogales, 1988). Clinically, the tumors may mimic a **friable endocervical polyp**. This tumor type, even when deeply invasive, appears to have a very favorable prognosis: as of 1993, no metastases have been reported (Jones et al, 1993). The association of this tumor type with a high grade squamous epithelial lesion (carcinoma in situ) has been reported by Young and Scully (1989).

Histology

On the **surface, the tumor forms delicate, slender, sometimes branching, papillary projections**, lined either by a single or stratified layers of cuboidal or columnar cancer cells, surrounding a connective tissue core often showing a marked inflammatory infiltrate (Fig. 12-16 A,B). The epithelial lining may contain mucin-producing cells or even goblet cells. The infiltrating portions of the tumors show well-formed, branching glands. The level of cytologic abnormality in the epithelial lining is modest with only slight nuclear enlargement and very rare mitoses.

Cytology

The key cytologic feature of these uncommon tumors is the presence of **numerous, tightly cohesive multilayered**

P.411

clusters of endocervical cells. The clusters are either **spherical**, with flattened cells at the periphery, corresponding to papillae of the tumor, or **irregularly shaped**, lined by columnar cells. The **nuclei** within the clusters are **somewhat enlarged** and **hyperchromatic** but these features can only be recognized by comparison with normal endocervical cells which are absent in these preparations (Fig. 12-16C,D). **Except for their large number and irregular configuration, the cell clusters may be readily mistaken for clusters of normal endocervical cells** obtained by brushing. Single cancer cells or rosettes have been reported as a rare event by Ballo et al (1996). The same authors reported that only 1 of 11 smears was initially diagnosed as endocervical adenocarcinoma; other diagnoses rendered comprised a wide spectrum of benign and malignant lesions. On review, however, 9 of 11 smears contained

the features of papillary villoglandular lesions. The difficulties with the recognition of this tumor were confirmed in reports by Novotny and Ferlisi (1997) and Chang et al (1999).

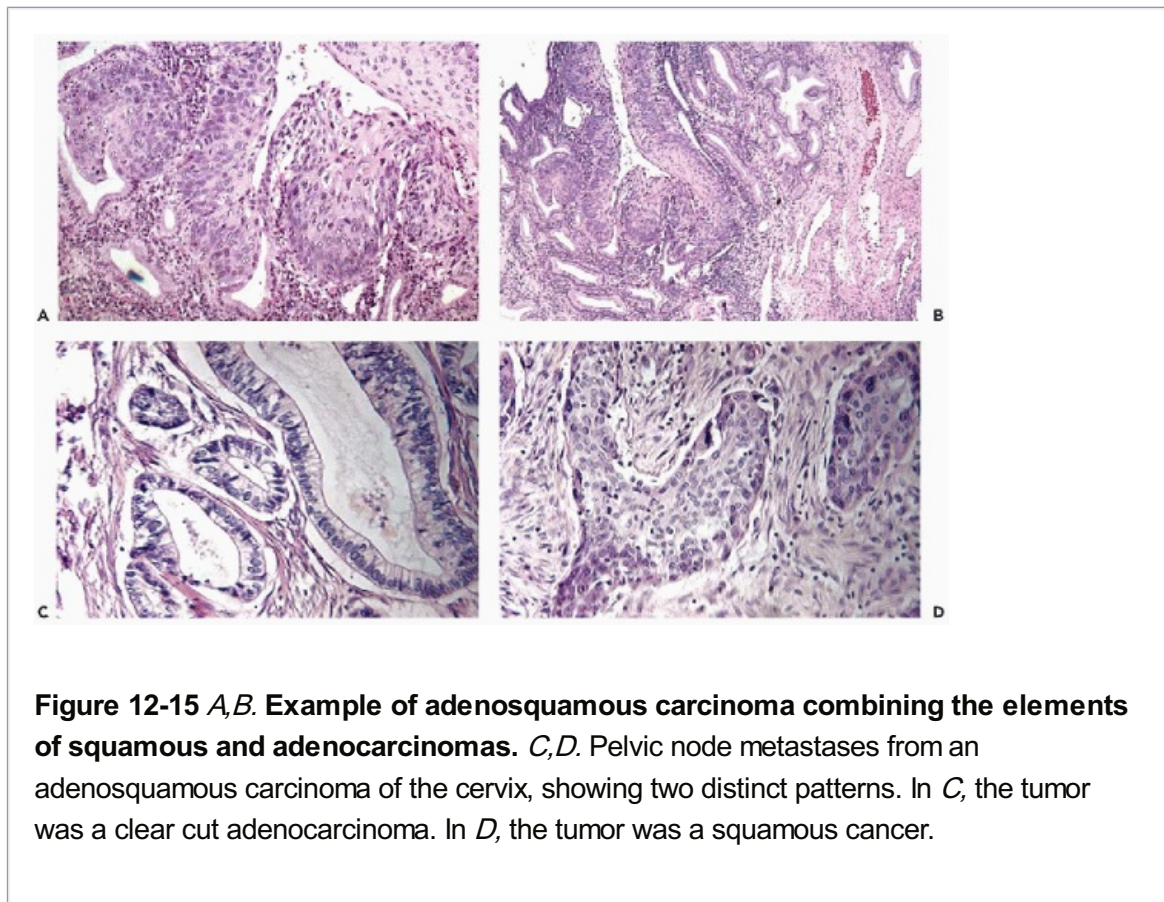

Figure 12-15 A,B. Example of adenosquamous carcinoma combining the elements of squamous and adenocarcinomas. C,D. Pelvic node metastases from an adenosquamous carcinoma of the cervix, showing two distinct patterns. In C, the tumor was a clear cut adenocarcinoma. In D, the tumor was a squamous cancer.

Serous Adenocarcinoma

These are very uncommon high grade tumors of the endocervix, mimicking the serous carcinoma of the ovary and similar tumors of the endometrium, and composed of cuboidal malignant cells with high nucleocytoplasmic ratio and marked nuclear abnormalities (Zhou et al, 1998) (also see Chaps. 13 and 17). We have not observed such tumors in our cytologic material and, to our knowledge, only one such case has been briefly reported (Nguyen, 1997).

Minimal Deviation Carcinomas (Adenoma Malignum)

Histology

Adenoma malignum is a rare form of endocervical adenocarcinoma, characterized by a **proliferation of very well differentiated, mucus-producing endocervical glands, closely resembling normal glands**. In their fully developed form, these tumors show an invasion of the cervical stroma by mucus-producing glands that vary in size yet show few, if any, cellular or nuclear abnormalities in gland lining (Fig. 12-17C,D). Mitotic activity is very low. The presence of **Paneth cells and cells with endocrine granules** has been reported in the lining of the endocervical glands (Fetissof et al, 1985). At the time of diagnosis, the entire thickness of the cervix is usually invaded by tumor so that the malignant nature of the lesion is beyond doubt. McKelvey and Goodlin, who first defined

P.412

the lesion in 1963, pointed out the **exceptional diagnostic difficulties in identifying the lesion in cervical biopsies** because of the unwillingness of the pathologists to entertain the

diagnosis of cancer on debatable evidence. Thus, **many of these tumors remain undiagnosed in the early stages until there is obvious clinical evidence of cancer**, sometimes with metastases. In 1969, Kese reported the association of this unusual tumor with **Peutz-Jeghers syndrome**, the latter consisting of skin pigmentation and hamomatous polyps in the gastrointestinal tract. Gallagher et al (1971), Gloor et al (1978), McGowan et al (1980), and Kaku et al (1985) also reported such cases. Another association of adenoma malignum is with **ovarian tumors of sex cord type** with annular tubules (Young et al, 1982). Only some of the adenoma malignum-type lesions show these associations, but it is advisable to keep these complications in mind at the time of diagnosis. Gilks et al (1989) failed to identify any immunohistologic features of diagnostic value in these rare tumors with poor prognosis.

Figure 12-16 Villoglandular papillary carcinoma of endocervix. *A,B.* The tissue lesion. *C,D.* Thick cohesive clusters of endocervical cells which, at higher magnification, failed to show any nuclear abnormalities. (*C,D:* Courtesy Dr. Mary Sidawy, George Washington University, Washington, DC.)

Cytology

The cells desquamating from adenoma malignum closely **resemble benign endocervical cells in shape and manner of exfoliation in clusters**. However, in our experience, **the cells and their nuclei are somewhat larger than normal and the clusters tend to be multilayered and crowded**. The clusters rarely allow a diagnosis, but the background of the smears often contains **detached, single tumor cells that are more spherical and have large but pale nuclei, provided with large, spherical or sometimes irregularly-shaped nucleoli** (Fig. 12-17A,B). Essentially similar findings were reported by Szyfelbein et al (1984) in three patients, two with Peutz-Jeghers syndrome.

The accurate cytologic diagnosis of this type of tumor is very difficult, matching the difficulty of the histologic diagnosis. As is often the case with cells derived from endocervical neoplasia, the differential diagnosis includes cells seen in acute endocervicitis, florid squamous metaplasia or repair, and cells from other forms of endocervical adenocarcinoma. Granter and Lee (1996)

reviewed the cytologic findings in seven patients. In only one case did the cervical smear lead to biopsy diagnosis. On review, cells similar to reactive endocervical cells were observed in five patients. The cytologic suspicion of disease must be confirmed by histologic evidence, which, as stated above, may be deceptive and difficult to interpret.

Mesonephric Carcinomas (Carcinomas Derived From Gartner's Duct)

Histology

These very rare cancers originate in the remnants of the wolffian ducts that are found in the ovaries, the tubes, the

P.413

stroma of the cervix, and vagina. They are characterized by proliferation of glandular structures of varying sizes, sometimes with small papillary projections. The component cells of these tumors are often large, with clear cytoplasm, and protrude from the gland lining in "hobnail" fashion.

Figure 12-17 Adenoma malignum (minimal deviation adenocarcinoma). *A.* A large cluster of endocervical cells with large nuclei and visible nucleoli. *B.* A scattering of single cells with similar features. *C.* The invasive pattern of the lesion. *D.* The make-up of glands which closely resemble normal endocervical glands.

These tumors have many similarities with vaginal and cervical carcinomas associated with diethylstilbestrol (DES) (discussed in Chap. 14). Gartner duct tumors are usually observed in adult women but occur also in adolescents. Because of their protected location within the stroma of the cervix, the diagnosis is often delayed until the tumor breaks into the lumen of the endocervical canal, although the prognosis appears to be somewhat better than that of endocervical adenocarcinoma. Several subtypes of these very rare tumors have been identified but this classification is irrelevant to this text (Ferry and Scully, 1990; Clement et al, 1995; Silver et al, 2001).

Cytology

Because these tumors originate in the body of the cervix, they are not accessible to cytologic sampling until they reach the surface of the endocervical canal. We have observed one such case in a 14-year-old girl many years ago. The cytologic presentation was that of an adenocarcinoma (Fig. 12-18A). Welsh et al (2003) observed abnormal endocervical cells in several patients with **remnants or hyperplasia of mesonephric ducts**.

However, there is some evidence that Gartner duct carcinoma may also have a long silent history prior to clinical manifestation of disease. This is illustrated in Fig. 12-18B-D. The original smear, obtained 4 years before the second, was interpreted as showing changes consistent with acute cervicitis or "repair" (Fig. 12-18B). The changes in the second smear (Fig. 12-18C), this time accompanied by spotting, were considered sufficient to warrant a biopsy, which revealed a Gartner duct carcinoma still confined to the lateral wall of the grossly normal cervix but involving the endocervical canal (Fig. 12-18D).

Mucoepidermoid Carcinomas

These very rare tumors mimic the well differentiated variant of mucoepidermoid tumors of the salivary glands and are, therefore, discussed separately from adenosquamous carcinomas (see above).

Histology

Occasional tumors of the cervix **composed of solid cords of eosinophilic epidermoid cells contain isolated, large, mucus-producing cells** (Fig. 12-19C,D). Sometimes, well formed glands, lined by a mixture of squamous and mucus-producing

P.414

cells, may be observed within such tumors. Hamperl and Hellweg (1957) pointed out that some mucus formation may be demonstrated in most epidermoid cancers of the cervix; however, the presence of single, large cells with mucus-distended cytoplasm is typical of mucoepidermoid carcinoma.

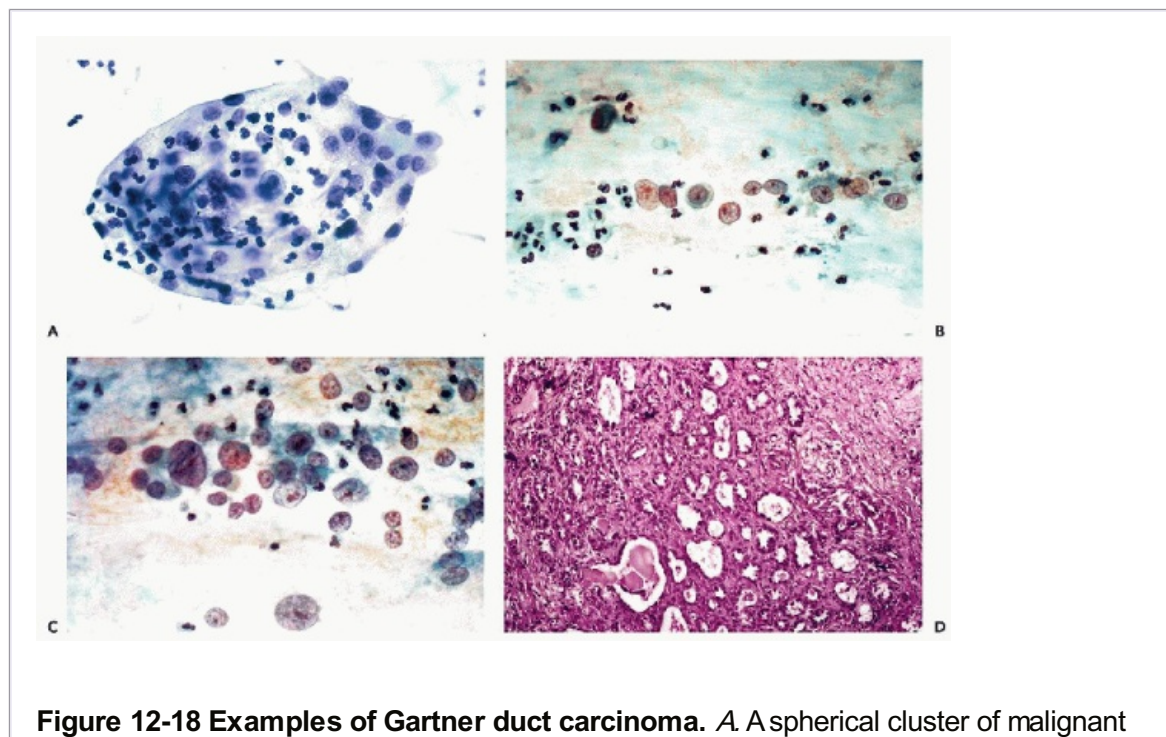

Figure 12-18 Examples of Gartner duct carcinoma. A. A spherical cluster of malignant

cells in a smear from a 14-year-old girl. *B,C*. Cytologic patterns of Gartner duct carcinoma from another patient, initially misinterpreted as “endocervicitis” or repair. *D*. Gartner duct carcinoma diagnosed by biopsy 4 years after the smears shown in *B* and *C* were obtained.

Cytology

There is no recorded experience pertaining to the cytologic presentation of these tumors. In a personally observed case courtesy of Dr. David Clark, the dominant abnormalities in the cervical smears were large, well-formed atypical endocervical cells with prominent nucleoli, more consistent with reactive atypia than an endocervical adenocarcinoma (Fig. 12-19A). Atypical squamous cells, singly or in small clusters, were also present (Fig. 12-19B). This evidence was insufficient for diagnosis of carcinoma but led to a diagnostic cervical biopsy (Fig. 12-19C,D).

Glassy-Cell Carcinomas

Histology

In 1956, Glucksmann and Cherry described a **radiotherapy-resistant variant of mucoepidermoid carcinoma** of the uterine cervix, composed of **sheets of large cancer cells with “ground-glass” appearance of the cytoplasm and infrequent droplets of mucicarmine positive material** (Fig. 12-20C,D). **The tumors also may form squamous “pearls.” The presence of large nuclei with particularly large nucleoli was noted.** Littman et al, in 1976, revived the term “glassy cell carcinoma” and generally confirmed the descriptions by Glucksmann and Cherry.

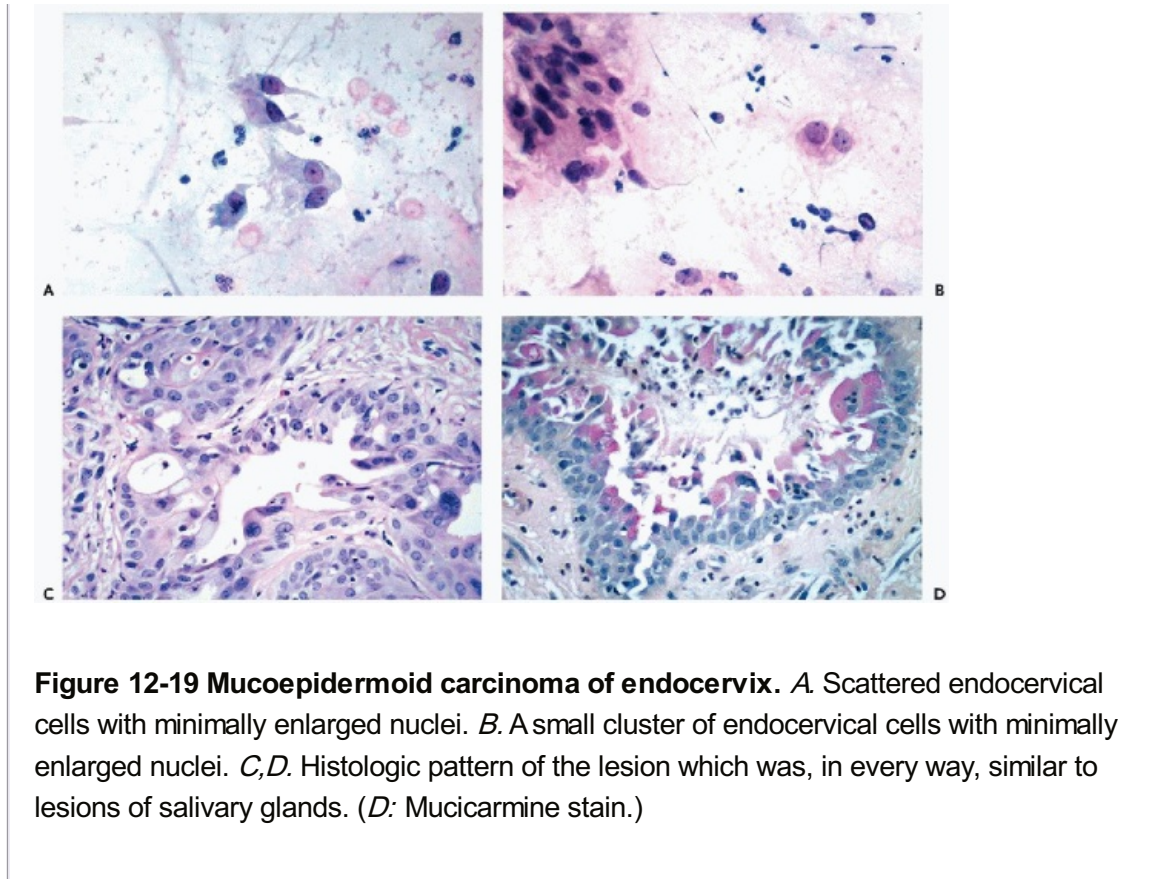

Although these tumors are uncommon and poorly defined, they nonetheless elicited a large number of publications, particularly in the 1980s, that is disproportionate to the frequency and clinical significance of this lesion. There are a few such cases reported in the American literature (Maier and Norris, 1982; Pak et al, 1983; Tamimi et al, 1988). The tumors, even in stage IB, have a poor prognosis, with only about 50% of patients having 5-year survival (Lotocki et al, 1992).

Cytology

It is a matter for considerable debate whether the glassy cell carcinoma is deserving of a separate classification or whether it is a minor and rare variant of poorly differentiated squamous carcinoma of endocervical origin. Nonetheless, glassy cell carcinomas shed large **cancer cells with faintly granular, delicately vacuolated cytoplasm and large vesicular nuclei with remarkably large, irregular eosinophilic nucleoli** (Fig. 12-20A,B). In Papanicolaou stain, **the large, usually single nucleoli stand out as large, pink intranuclear**

P.415

bodies and may be mistaken for inclusions of herpesvirus or Reed-Sternberg cells in Hodgkin's disease (see Chaps. 10 and 31).

Pak et al (1983) reported a substantial number of false-negative smears in patients with glassy cell carcinoma wherein cancer cells with the characteristic nucleolar enlargement were found on review in 4 of 12 samples. Nunez et al (1985) and Chung et al (2000) also confirmed the presence of unusually large nucleoli as a characteristic feature of glassy cell carcinoma.

Very Rare Tumors

Clear-cell carcinomas are usually associated with vaginal adenosis and clear cell carcinoma of the vagina (discussed in Chap. 14).

Adenoid cystic carcinoma, adenoid basal carcinoma (epithelioma), lymphoepithelioma and other unusual tumors of the uterine cervix are discussed in Chapter 17.

DIFFERENTIAL DIAGNOSIS. ENDOCERVICAL ADENOCARCINOMA VERSUS OTHER TUMOR TYPES

- In the presence of clusters of small malignant cells, without distinguishing features, similar to those occurring in high grade squamous lesions of endocervical origin, it is not possible to separate an adenocarcinoma from a squamous cancer of endocervical origin on cytologic preparations. Still, it is advisable to suggest that the tumor, whatever its type, is likely to be located in the endocervical canal.
- Poorly differentiated squamous (epidermoid) high grade precursor lesions originating in the endocervical canal, may sometimes be represented in smears by large, columnar cancer cells (see Figs. 11-35 and 11-53).
- It may be difficult to separate an endocervical from endometrial adenocarcinoma, though the latter is usually composed of smaller cancer cells (see Chap. 13). Several histochemical approaches have been tried. Thus, Cohen et al (1982) proposed that

carcinoembryonic antigen (CEA) and mucin are expressed in endocervical adenocarcinoma but not in endometrial carcinoma. A subsequent study by Cooper et al (1987) failed to confirm these findings. The issue was revived recently, again with insecure results (McCluggage et al, 2001; Kamoi et al, 2002). It is evident that, in such cases, careful clinical history and adequate histologic sampling cannot be replaced by other laboratory methods.

■ **Metastatic adenocarcinoma, particularly of colonic origin,**

P.416

that shed large columnar cancer cells may mimic endocervical adenocarcinoma (see Chap. 17).

- It has been reported that **abnormal cells observed in tubal and tubo-endometrioid metaplasia, and particularly in endometriosis, may mimic cells of adenocarcinoma** (see recent review by Cangiarella and Chhieng, 2003). This issue has been discussed at length in Chapters 10 and 11. It is my judgment that, **in most such cases, the abnormal cells reflect a significant abnormality of premalignant or malignant nature that may be observed in the upper reaches of the endocervical canal.**
- The main points of differential diagnosis of adenocarcinoma of the cervix are shown in Tables 12-1 and 12-2.

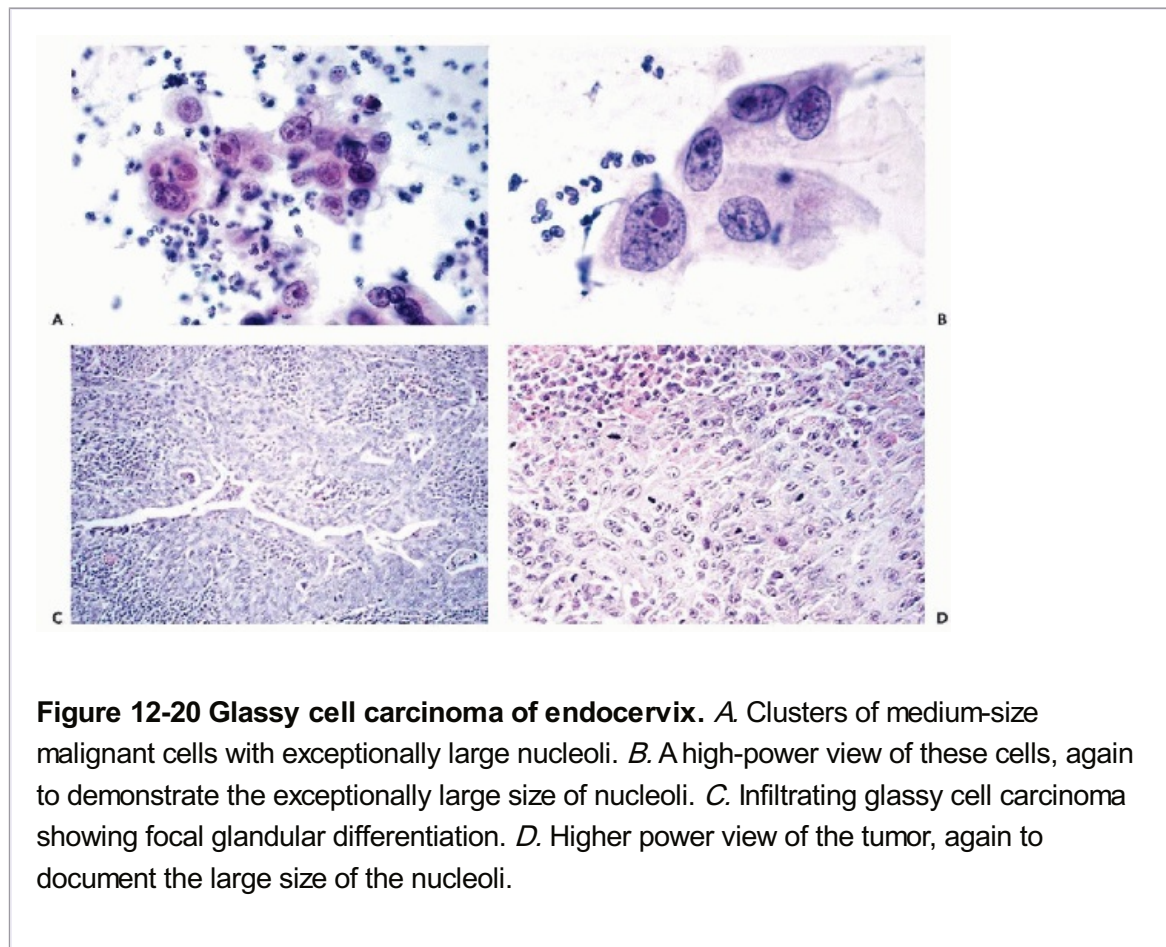

Figure 12-20 Glassy cell carcinoma of endocervix. *A.* Clusters of medium-size malignant cells with exceptionally large nucleoli. *B.* A high-power view of these cells, again to demonstrate the exceptionally large size of nucleoli. *C.* Infiltrating glassy cell carcinoma showing focal glandular differentiation. *D.* Higher power view of the tumor, again to document the large size of the nucleoli.

ACCURACY OF CYTOLOGIC DIAGNOSIS OF ENDOCERVICAL ADENOCARCINOMA

The diagnosis of adenocarcinoma of the endocervix may cause substantial difficulties, either

because the subtle changes in the endocervical cells are mistaken for benign events or, because in many cases, adenocarcinoma is obscured by an adjacent neoplastic squamous lesion.

In 1985, Saigo et al reported on 58 patients with endocervical adenocarcinoma, 18 of who were asymptomatic, with a remarkable diagnostic accuracy of 91%. These results appear to be unmatched. There are few recent surveys of diagnostic accuracy based on contemporary techniques (endocervical brushings, liquid preparations). Hayes et al (1997) reported the cytologic findings on 131 patients with histologically documented adenocarcinomas of various stages, including adenocarcinoma in situ (AIS) but excluding minimal deviation tumors. In 18 patients, the smears showed no abnormalities whatsoever. In 46 cases, only a HGSIL was detected. In the remaining cases, significant abnormalities were observed, as described above in this chapter. Most importantly, perhaps, **the authors were unable to separate AIS from invasive adenocarcinoma**, in keeping with the writer's experience.

Soofer and Sidawy (2000) reported that women with smears diagnosed as “reactive cell changes” were more likely to develop squamous intraepithelial lesions than negative controls. No adenocarcinomas were found in this study. Selvaggi (2002) reported on similarities and differences between AIS and HGSIL with endocervical gland involvement in liquid-based cytology. She noted that “cell polarity” was maintained in AIS and lost in HGSIL. Rosettes and palisading were observed in AIS but not in HGSIL. Most other

P.417

features of cancer cells, including the presence of abnormal columnar cells, were common to both lesions. Other surveys (Kristensen et al, 1991; Krane et al, 2001) disclosed a high rate of false negative diagnoses in 30% to 50% of cases. Negri et al (2003) proposed that

immunostaining with an antibody to the tumor suppressor gene p16^{INK4A} is helpful in the diagnosis of adenocarcinoma in liquid preparations. Lack of reproducibility of cytologic diagnoses, among experienced observers in benign and malignant endocervical cell samples, was recently emphasized in a study by Simsir et al (2003). The role of human papillomavirus testing in identification of endocervical cancer is insecure at this time (Cangiarella and Chhieng, 2003).

TABLE 12-1 BENIGN CYTOLOGIC ABNORMALITIES THAT CAN BE MISTAKEN FOR ENDOCERVICAL ADENOCARCINOMA

Condition	Most Characteristic Single Feature	Compared With Adenocarcinoma
“Repair” (Chap. 10)	<i>Flat</i> sheets of endocervical cells with large nucleoli; normal nucleocytoplasmic ratio	Multilayered sheets in spherical (papillary) configuration. Large nucleoli uncommon
Acute or chronic endocervicitis or IUD wearers or pregnancy	Enlarged, usually single endocervical cells with enlarged, slightly hyperchromatic nuclei and nucleoli; see repair above	Clinical history is important. Similar cells may occur in adenocarcinoma - search for other evidence of

(Chaps. 8 and 10)		disease, otherwise classify as endocervical cell atypia (AGUS)
Tuboendometrial metaplasia (Chap. 10)	Ciliated cells. If there are nuclear abnormalities, a malignant process cannot be ruled out	Rare ciliated cells may occur in brush specimens
Benign endometrium in brush specimens (Chaps. 8 and 14)	Usually a tight cluster of uniform small cells, sometimes whole fragments of endometrium. If nuclear abnormalities are present, endometrial or endocervical neoplastic abnormalities cannot be ruled out	Usually the cells of endocervical carcinoma are of variable sizes, larger and of columnar or cuboidal shape

TABLE 12-2 MALIGNANT LESIONS THAT CAN BE MISTAKEN FOR ENDOCERVICAL ADENOCARCINOMA

Differential Diagnosis	Distinguishing Features
High grade squamous lesions originating in endocervical epithelium (Chap. 11)	May have identical presentation to endocervical adenocarcinoma. Histologic study is essential
Endometrial carcinoma (Chap. 13)	Usually the cells of endometrial carcinoma are smaller and of spherical configuration
Endometrial adenoacanthoma or adenosquamous carcinoma (Chap. 13)	May have very similar presentation to endocervical adenosquamous carcinoma. Histologic study is essential
Metastatic cancer (Chap. 17)	Clinical history is essential. Metastatic colonic carcinoma may mimic endocervical adenocarcinoma (large, columnar, mucus-producing cancer cells). Other metastatic cancers are usually composed of smaller cells.

In summary, precise cytologic diagnosis of endocervical

P.418

adenocarcinoma is fraught with difficulties which have been reported from a large number of laboratories from several countries. The difficulties in separating benign reactive endocervical changes from adenocarcinoma and the presence of squamous neoplastic lesions obscuring the presence of adenocarcinoma are the principal culprits. It follows that aggressive clinical follow-up of patients with atypical endocervical cells may result in a better diagnostic performance. Moriarty and Wilbur (2003) recently expressed the hope that molecular markers may be helpful in this regard.

Proliferative Disorders and Carcinoma of the Endometrium

With a marked decrease in the rate of invasive cancer of the uterine cervix, cancer of the endometrium has become **the most common cancer of the female genital tract diagnosed in the United States, with the second highest mortality rate after ovary**. The death rate from endometrial carcinoma increased substantially between the years 1990

P.423

and 2000 (Greenlee et al, 2000). A major increase in the rate of endometrial cancer has also been observed in other countries, such as Japan (Sato et al, 1998) and Canada (Byrne, 1990). Therefore, the primary goal of diagnostic cytology of the endometrium should be the **diagnosis of clinically unsuspected endometrial carcinoma of low stage and, hence, amenable to cure**. In a study of a large group of asymptomatic women, it has been documented by Koss et al (1981, 1984) that **approximately 8 per 1,000 peri- and postmenopausal women harbor such lesions**. The study is described in detail further on in this chapter. Prior to this work, **primary** cytologic diagnosis of **occult endometrial carcinoma** was rarely reported, particularly when compared with the wealth of material on the uterine cervix. Twenty-two of 102 endometrial cancers, diagnosed in cervicovaginal smears, occurred in asymptomatic women (Koss and Durfee, 1962). In a series of 285 endometrial carcinomas reported by Reagan and Ng (1973), there were only 18 cases with primary diagnosis by cytology. Only a few additional cases may be found in the older case reports, including some illustrated in Papanicolaou's *Atlas* (1954). It is quite evident that detection of early endometrial carcinoma has not reached the level of interest equal to detection of mammary or cervical cancer. For whatever reasons, this important disease has been neglected by the society.

Endometrial cytology belongs to the most difficult areas of morphology. There are two main reasons for it:

- **The difficulties with obtaining a representative sample of the endometrium**
- **The difficulties in the interpretation of the cytologic evidence and the recognition of normal and abnormal cells of endometrial origin**

This chapter is dedicated to the description of endometrial cytology in health and disease, compared with histologic observations.

CYTOLOGY OF ENDOMETRIUM IN HEALTH AND BENIGN CONDITIONS

Routine Cervicovaginal Samples

The recognition of normal glandular and stromal endometrial cells in **routine cervicovaginal samples** plays a critical role in the diagnosis of endometrial abnormalities. Therefore, a brief recall of commonly observed cytologic findings is summarized here.

Normal Findings

Childbearing Age

As described and illustrated in Chapter 8, glandular and stromal endometrial cells are normally found in routine cervicovaginal samples during **menstrual bleeding** and for 2 to 3 days thereafter. As a rule, **the finding of endometrial cells, regardless of morphology, after the 12th day of the cycle (considering the first day of bleeding as the first day of the cycle) must be considered abnormal**. Depending on the clinical situation (e.g., patient's age, clinical

history, risk factors for endometrial cancer; see discussion below), **the patient may be deserving of follow-up or further investigation**, although, in most such women, no significant lesions are found and the endometrial cells are most likely a variant of normal shedding.

In endocervical brush specimens, normal endometrial cells, derived from the lower uterine segment (LUS) of the endometrial cavity, may be observed, regardless of day of cycle, and should not be a cause for alarm, although incidental endometrial abnormalities may sometimes be recognized in such samples (see below). De Peralta-Venturino et al (1995) and Heaton et al (1996) stressed that material obtained from LUS may contain large fragments of endometrial glands and stroma that may be mistaken for carcinomas of endometrial or endocervical origin and benign entities, such as **endometriosis**.

Menopause

In postmenopausal women, the presence of endometrial cells in routine smears must be considered, a priori, abnormal and calls for further investigation of the endometrium.

Benign Conditions and Disorders

Pregnancy

Endometrial cells are practically never seen in normal pregnancy. The **decidual cells** and particularly the large **Arias-Stella cells with dark, polyploid nuclei, either derived from the endometrium or the endocervix**, both discussed and illustrated in Chapter 8, may be mistaken for endometrial cancer cells in cervicovaginal material. **Pregnancy does not rule out endometrial cancer**. On the rarest occasion, we have observed **normal pregnancy occurring in women with endometrial carcinoma** documented by prior biopsy and confirmed postpartum. A similar case was described by Kowalczyk et al (1999) who also summarized the very scanty literature on this topic. Apparently, normal implantation of the ovum may occur under these circumstances. Also on record are several cases of normal pregnancies occurring in women with documented endometrial hyperplasia (Kurman et al, 1985).

Intrauterine Contraceptive Devices

As has been described in Chapters 8 and 10, the wearers of intrauterine contraceptive devices (IUDs) may shed endometrial cells at midcycle. Occasionally, such cells have a **vacuolated cytoplasm and poorly preserved nuclei that may appear to be somewhat enlarged and slightly hyperchromatic and that may be mistaken for cells of an adenocarcinoma** (Fig. 13-1). Sometimes, the cervicovaginal smears may also contain **inflammatory cells and macrophages**, creating a cytologic background, not unlike that seen in endometrial carcinoma (see below). The young age of most wearers of IUDs is usually against this latter diagnosis. Another potential source of error is the presence of **endocervical "repair" caused by IUD, in which the reactive endocervical cells may be mistaken for abnormal endometrial cells** (see Chapter 10; and comments below).

An important **histologic** finding in wearers of the IUD

P.424

is the presence of **small, round foci (morulae) of squamous cells** in the superficial layers of the endometrium, presumably a form of squamous metaplasia, induced by the mechanical effect of the devices. Lane et al (1974) suggested that this abnormality is transient, although evidence of reversal of this process is poor. These abnormalities are very rarely seen and **should not be mistaken for an endometrioid carcinoma with squamous component or an adenoacanthoma** (see below).

Figure 13-1 Benign endometrial cells in cervicovaginal smears. *A.* A small cluster of endometrial cells, difficult to identify at this magnification. *B.* High-power view of a cluster of endometrial cells in an IUD wearer. It may be noted that several of the cells have vacuolated cytoplasm. *C.* A small cluster of endometrial stromal cells showing mitotic activity. These cells are extremely difficult to recognize in routine material.

Signet-Ring Cells

Iezzoni and Mills (2001) described 5 symptomatic patients in whom routine endometrial tissue samples contained aggregates of **benign signet ring cells** with small nuclei. The authors traced these cells to decidualized stromal cells. There is no record of such cells in cytologic samples.

Endometrial Metaplasia

Johnson and Kini (1996) described the presence of atypical endometrial cells in the presence of eosinophilic, papillary, squamous and tubal metaplasia of the endometrium. Five of seven patients were postmenopausal and three had abnormal bleeding. The nature of this observation is questionable and it cannot be excluded that some of the patients had a poorly defined neoplastic process.

Exogenous Hormones

Contraceptive Hormones

Women receiving this medication occasionally bleed or spot and shed **endometrium at mid-cycle (breakthrough bleeding)** until the dosage is adjusted. Long-term usage of these agents may result in **decidua-like changes** in endometrial stroma, followed by **atrophy**; neither of these conditions is known to cause endometrial shedding. Abnormalities of nuclei of **endocervical cells** may occur **in women receiving progesterone-rich contraceptive agents** (see Chapter 10). Accurate clinical history is helpful in preventing errors but, in some cases, may require biopsies for clarification.

Steroid Hormones

In patients receiving **steroid hormones, particularly estrogens**, two important cytologic changes may be observed.

- In postmenopausal women, the **level of maturation of the squamous cells may increase** (see Chapter 9), resulting in a smear pattern that is sometimes seen in endometrial hyperplasia and early endometrial carcinoma (see below).
- The patients may shed endometrial cells during medication and, particularly, immediately after withdrawal of estrogens (**withdrawal bleeding**). **In the absence of clinical data in**

postmenopausal women, the presence of endometrial cells may cause an unnecessary alarm. The potential carcinogenic effects of estrogens and tamoxifen are discussed below, in conjunction with epidemiology of endometrial carcinoma.

For further comments on effects of steroid hormones, see Chapter 9.

P.425

Regenerating Endometrium

Following a curettage or other form of trauma to the endometrium, the healing of the endometrial defect leads to an **intensive proliferation of the surface epithelium, followed by formation of endometrial glands by invagination of the surface epithelium. In histologic sections, the surface epithelium is composed of large cells of variable sizes with hyperchromatic nuclei, sometimes with large nucleoli, and with numerous mitoses.** In **endometrial aspiration smears**, the large and poorly preserved endometrial glandular cells have a **vacuolated cytoplasm, sometimes infiltrated with polymorphonuclear leukocytes and enlarged hyperchromatic nuclei** (Fig. 13-2). These cells may be mistaken for cancer cells. In this situation, it is advisable to wait until after a normal menstrual bleeding has taken place (usually about 6 weeks after the procedure) before attempting to judge the status of the endometrium.

Inflammatory Lesions

Purulent endometritis resulting from bacterial infection may follow childbirth or abortion. The cervicovaginal smears may disclose **pus and debris**. Smears obtained by direct **endometrial sampling** show acute inflammation and necrosis. Fragments of endometrial glands with degenerated, blown-up cells may be difficult to distinguish from cells of necrotizing endometrial carcinoma. The differential diagnosis may have to rest on clinical history and histologic evidence.

Figure 13-2 Regenerating endometrium 3 days after curettage. All four photographs from the same 20-year-old patient. *A.* A large cluster of endometrial cells, some showing vacuolization. *B.* A cluster of endometrial cells with hyperchromatic nuclei, some showing nucleoli and cytoplasmic vacuoles. *C.* In addition to the features described for *B*, the cytoplasm of many of the vacuolated cells is populated by polymorphonuclear leukocytes. *D.* Another example of regenerating endometrial cells in the background of blood and inflammatory reaction.

Chronic nonspecific endometritis is an uncommon condition in which there is an infiltration of the endometrium by lymphocytes, plasma cells, and macrophages, sometimes with atrophy of the glands. The condition is virtually never recognized in cytologic samples.

Tuberculosis of the Endometrium

A resurgence of tuberculosis in patients with immune deficiency caused by AIDS has revived interest in this disease in the developed countries. The disease is common in the developing world.

Histology

Advanced tuberculosis of the endometrium may be associated with a **marked disruption of the endometrial gland pattern. Atypical glandular proliferation may be very**

P.426

marked and misleading to the point of suggesting a carcinoma. Only the presence of **granulomas** identifies the condition. The diagnosis should be confirmed by demonstration of tubercle bacilli. The clinical presentation of endometrial tuberculosis is not helpful because the symptoms, such as metrorrhagia, may suggest cancer clinically.

Cytology

The abnormalities of the endometrial glands are also reflected in cervicovaginal smears. Sheets of **large endometrial glandular cells of uneven size and with pronounced nuclear hyperchromasia may suggest endometrial cancer** (Fig. 13-3). In such cases, the differential diagnosis between tuberculosis and endometrial carcinoma may prove to be extremely difficult, if not impossible, on cytologic grounds. To our knowledge, **neither epithelioid cells nor Langhans'-type giant cells** have been so far identified in endometrial material as they have been in cervical smears (see Chap. 10). The presence of **multinucleated histiocytes in the cervicovaginal smears is of no diagnostic value in the diagnosis of tuberculosis.**

Figure 13-3 A case of endometrial tuberculosis. Abnormal endometrial cells in the vaginal pool smear (*A*) and in an endometrial aspiration (*B*). Note the hyperchromatic nuclei and the scanty cytoplasm. The histologic sections of the endometrium under low power (*C*) and high power (*D*) disclose atypical endometrial glands as the source of cellular abnormalities. Note the tubercle in *C*. (Tissue section from Dr. Jacob M. Ravid.)

Sarcoidosis

This granulomatous disease of unknown etiology may affect the endometrium (Chalvardjian, 1978; Skehan and McKenna, 1986; Elstein et al, 1994). **Noncaseating granulomas**, characteristic of this disorder, are observed in histologic material but, so far, have not been observed in cytologic material. For a description of cytologic presentation of pulmonary sarcoidosis, see Chapter 19.

Viral Endometritis

Astin and Askin (1975) and Wenckebach and Curry (1976) described endometritis due to **cytomegalovirus**. The tissue showed evidence of chronic inflammation and formation of lymphocytic deposits, in addition to large cells containing the characteristic viral inclusions. Wenckebach and Curry confirmed the diagnosis by electron microscopy. Duncan et al (1989) described a case of **necrotizing endometritis**

P.427

associated with herpesvirus infection. Neither of these viral infections of the endometrium have been reported in cytologic writing.

Other Inflammatory Disorders

A case of **malacoplakia** was described by Thomas et al (1978). For further comments on histologic and cytologic presentation of malacoplakia, see Chapter 22.

Cytologic Atypias Associated With Endometriosis

Several observers reported that brush samples in cases of endocervical or transformation zone endometriosis may contain abnormal glandular cells that may mimic either an endocervical or an endometrial carcinoma (Hanau et al, 1997; Mulvany and Surtees, 1999; Lundeen et al, 2002).

The abnormalities allegedly caused by endometriosis were illustrated in Figure 11-35C, as examples of atypical glandular cells of unknown significance. In the judgment of this writer, cytologic diagnosis of endometriosis cannot be established. The changes described are most likely brushartifacts with inadequate correlation with histologic findings.

Endometrial Abnormalities Associated With Uterine Leiomyomas

Leiomyomas are by far the most common benign tumors of the uterine corpus. The tumors, composed of bundles of smooth muscle and connective tissue, richly supplied with blood vessels, are often multiples and may reach large sizes. Hemorrhagic necrosis or infarction are known complications of leiomyomas. Many women with benign leiomyomas of the uterus experience episodes of **abnormal uterine bleeding**. The bleeding is attributed to various causes, such as the inability of the uterus to contract because of interference of leiomyoma with myometrial functions, or to submucosal position of the leiomyoma, causing focal ulceration of the endometrium. Objective evidence for these events is conspicuously absent. However, there is evidence that, at least in some women, the bleeding may be caused by **endometrial hyperplasia**, which is present in about 50% of women with leiomyomas (Deligdisch and Loewenthal, 1970). Both these disorders (hyperplasia and leiomyomas) may have a common denominator, namely, hormonal imbalance due to preponderance of estrogens. In such cases, the **cytologic presentation is similar to other forms of endometrial hyperplasia** (see below).

ENDOMETRIAL POLYPS

Benign endometrial polyps may occur in any adult woman but are more common in the fifth decade of life and are a known cause of abnormal uterine bleeding and endometrial shedding. The tumors may originate in any part of the endometrial cavity and may vary in diameter from a few millimeters to several centimeters. The polyps, which may be single or multiple, may be broad-based or pedunculated and sometimes may protrude through the external os of the uterine cervix. **Atypia of endometrial glands is common in polyps and may account for abnormalities of endometrial cells in direct endometrial samples** (see below). Also, **endometrial carcinomas may originate in polyps**. The uncommon **mesodermal mixed**

tumors of endometrium may **originate in or mimic endometrial polyps** (see Chapter 17).

Histology

The benign polyps consist of a stroma resembling normal endometrial stroma intermingled with connective tissue that is sometimes hyalinized. The polyps are sometimes richly vascularized, with vessels present near the surface. The epithelial surface lining usually resembles proliferative endometrium but, in polyps originating in the lower uterine segment, it is occasionally composed of columnar cells, resembling normal endocervical lining. Occasionally, the epithelial cells are ciliated. Endometrial glands of variable sizes and shapes are present within the stroma. The epithelial lining of the glands is usually nonsecretory in type and does not participate in the cyclic changes. **Atypical endometrial glands**, lined by cells with enlarged nuclei and nucleoli mimicking glands observed in atypical hyperplasia, are fairly common in polyps (Fig 13-4D).

Cytology

An accurate cytologic diagnosis of an endometrial polyp is impossible in cervicovaginal samples. Occasionally, **clusters or single endometrial cells** are noted during the secretory phase of the cycle when endometrial cells should not be present, or in postmenopausal women (Fig. 13-4A-C). In postmenopausal women, the cytologic findings may be mistaken for an endometrial carcinoma. This error is **unavoidable**. Abnormalities mimicking carcinoma are also observed in **direct endometrial samples**, as described in detail below.

Large, protruding **polyps, pressing on the endocervical epithelium, may elicit a florid squamous metaplasia or “repair” reaction** (see Chapter 10). **Endometrial carcinomas, originating in polyps, have the same cytologic presentation as primary endometrial cancer** (see below).

Atypical polypoid adenomyoma is a rare and presumably benign type of endometrial polyp wherein markedly atypical proliferation of endometrial glands may occur (summary in Young et al, 1986). The possibility that these lesions represent an early stage of a mesodermal mixed tumor cannot be ruled out (see Chapter 17). There is no information on their cytologic presentation.

ENDOMETRIAL ADENOCARCINOMA

As described in the opening paragraphs of this chapter, endometrial carcinoma is, at the time of this writing (2004), the most common form of genital cancer. Partridge et al (1996) observed that the mortality rate from this disease is high and that advancing age, minority status, and low income

P.428

had a negative impact on survival. These authors deplored the absence of acceptable early detection systems. Such systems do exist, as narrated below, but their implementation and societal acceptance are thoroughly lagging when compared with carcinoma of the uterine cervix and female breast.

Figure 13-4 Endometrial polyp in a markedly obese 56-year-old woman. *A, B.* Clusters of endometrial cells against a background of high maturation of squamous cells. *C.* Large, endometrial cells with markedly vacuolated cytoplasm, granular nuclei, and occasional nucleoli. The endometrial cells show cytoplasmic and nuclear features consistent with endometrial adenocarcinoma. *D.* Endometrial polyp in the same patient.

Some of the reasons for a marked increase in the rate of this disease are discussed here.

Epidemiology

The constant growth and disintegration of the endometrium during the menstrual cycles of the childbearing age constitute a terrain that is not favorable to neoplastic growth and accounts for the rarity of endometrial cancer in women prior to menopause. **The absence of cyclic desquamation after the menopause or an arrest of endometrial turnover because of hormonal imbalance are important risk factors in the formation of endometrial carcinomas and their precursor lesions.** Examples of naturally occurring conditions leading to hormonal imbalances are the **Stein-Leventhal syndrome** and similar disorders of ovulation (see Chapter 9) or **estrogen-producing ovarian tumors (granulosa cell tumors and thecomas)**. Endometrial carcinoma has also been observed in the presence of ovarian dysfunction associated with masculinizing features (Koss et al, 1964).

Risk Factors

Exogenous Estrogens

In the late 1960s and in the 1970s, a statistically significant increase in the rate of endometrial carcinoma has been observed in many institutions throughout the United States. Smith et al, Ziel and Finkle simultaneously pointed out in 1975 that **widespread administration of conjugated and nonconjugated exogenous estrogens** to alleviate menopausal symptoms and prevent osteoporosis **was statistically associated with this increase.** Mack et al (1976) calculated the risk ratio for endometrial carcinoma in estrogen users when compared with nonusers at 8.0 times, and for conjugated estrogens at 5.6 times; these investigators also demonstrated a dose-related effect on endometrial carcinoma. In a study by a writers group for the PEPI Trial (1996), the administration of unopposed estrogens was shown to cause endometrial hyperplasia and occasional adenocarcinoma. The effect could be prevented by the administration of progesterone. Exogenous estrogens have been shown to be associated with endometrial carcinoma, even in the absence of ovarian function, for example in ovarian agenesis (Gray et al, 1970;

P.429

Cutler et al, 1972) or in Sheehan's syndrome (Reid and Shirley, 1974).

Although the evidence is substantial that estrogens may cause endometrial carcinoma, it has been shown that such lesions observed in estrogen-treated patients are usually **fully curable**,

low-grade and low-stage cancers (Robboy et al, 1982). Horwitz and Feinstein (1978) addressed this issue and reported on the status of peripheral endometrium in a case control study of 233 postmenopausal women, 112 of whom had endometrial carcinoma. Peripheral, simple endometrial hyperplasia was more commonly observed with grade 1 cancer among estrogen users than in cancer of higher grades among nonusers of estrogen. The authors concluded that “**it was likely that many otherwise asymptomatic tumors might have remained undetected except for the manifestations of the estrogen-related comorbid condition**” (hyperplasia). The observation was repeated by Horwitz et al (1981) who proposed that the effect of estrogens on endometrium is indirect: the drugs cause endometrial hyperplasia and, hence, uterine bleeding that leads to curettages and results in incidental discovery of small foci of early endometrial cancer. In fact, in our own study of occult endometrial carcinomas, estrogen treatment has not been shown to be a risk factor except for women with lower than average weight. It was hypothesized that this observation may perhaps be explained by the inability of this group of women to store the estrogens in their subcutaneous fat, resulting in more direct action on the endometrium (Koss et al, 1984; see below). The use of either estrogen therapy or estrogens combined with progesterone, also **increases the risk of breast cancer** (Colditz et al, 1995; Schairer et al, 2000) (see Chap. 29).

Tamoxifen

Tamoxifen is a steroid agent best characterized as an estrogen agonist or estrogen-receptor modulator, which blocks estrogen receptors in a variety of tissues and is now extensively used for **prevention and treatment of breast cancer** (summary in Osborne, 1998). The drug has several side effects affecting the female genital tract and, specifically, the endometrium.

Figure 13-5 Endometrial atypia associated with Tamoxifen. Endometrium in a 69-year-old woman receiving Tamoxifen for 5 years. Marked nuclear abnormalities of endometrial surface epithelium are seen under scanning (A) and higher (B) magnifications in an endometrial aspirate.

- **It induces maturation of squamous cells in postmenopausal women with atrophic genital tract** (Athanassiadou et al, 1992; Abadi et al, 2000).
- It has a stimulatory effect on the endometrium and has been recognized as a **cause of abnormal endometrial proliferative processes, including polyps, hyperplasias, and carcinoma** (Silva et al, 1994; Assikis and Jordan, 1995; Barakat, 1996; Fisher et al, 1994). The risk appears to be greater for obese women (Bernstein et al, 1999). Sporadic cases of mesodermal mixed tumors were also observed (Bouchardy et al, 2002; Wysowski et al, 2002; Wickerham et al, 2002). Common sense would suggest that the status of the endometrium should be determined in all women prior to tamoxifen therapy.

Measuring the thickness of the endometrium by ultrasound is a favored method of follow-up of patients receiving tamoxifen and other hormones (Achiron et al, 1995; Levine et al, 1995; Hann et al, 1997). It has been suggested that endometrial thickness of 8 mm or more should trigger an endometrial investigation by biopsy or curettage. Langer et al (1997), using the thickness of 5 mm as a trigger for endometrial biopsies in women receiving estrogen replacement therapy, noted that at this level of endometrial thickness, the technique has a very

poor positive predictive value but a high negative predictive value for important endometrial disorders.

Cytologic Observations in Tamoxifen Users

The information on the use of cytologic techniques to determine the status of the endometrium in tamoxifen-treated patients is scarce. Yet, anecdotal evidence based on personal observations of a few patients by endometrial sampling has shown that, **after a few years of medication, significant nuclear abnormalities may occur in glandular endometrial cells, that differ significantly from patterns of endometrial hyperplasia or carcinoma and most likely represent tamoxifen-induced endometrial atypia** (Fig. 13-5). Abadi et al (2000), in a study encompassing a small number of patients treated with tamoxifen, some of whom developed

P.430

endometrial carcinoma, noted that **the presence of endometrial cells and an increase in macrophages in cervicovaginal smears**, correlated in a statistically significant fashion with endometrial cancer.

Other Hormones

Endometrial carcinoma has been observed in approximately 0.05% of women treated with a variety of hormones for carcinoma of the breast (Hoover et al, 1976). **Hormonal contraceptive agents** usually cause endometrial atrophy. It is not known, at this time, whether these agents may also contribute to the genesis of endometrial cancer, although a few such cases have been recorded (Silverberg and Makowski, 1975).

Radiotherapy

Malignant tumors of the endometrium (carcinomas and occasionally mesodermal mixed tumors) have been observed in patients who received a **curative dose of radiation for invasive carcinoma of the uterine cervix** (Fehr and Prem, 1974).

Clinical Risk Factors

Carcinoma of the endometrium has been traditionally thought to be associated with **diabetes, obesity, hypertension, a past history of abnormal menses, and late menopause** (Wynder et al, 1966; Elwood et al, 1977). Our own epidemiologic studies of asymptomatic women with occult carcinoma failed to confirm these observations (Koss et al, 1984) but this cohort may have differed from symptomatic women who have been the common target of such studies. The only statistically significant factor in the Koss study was **delayed onset of menopause** (see Table 13-8). The full extent of the clinical epidemiology of the disease is deserving of further studies comparing symptomatic with asymptomatic patients.

Clinical Symptoms: Application of Cytologic Techniques

The principal clinical symptom associated with endometrial carcinoma is abnormal bleeding. Endometrial carcinoma is rare in women below the age of forty. **Any woman 40 years of age or older who shows clinical evidence of abnormal uterine bleeding for which no obvious cause can be found by obstetrical history or on clinical examination, should be, a priori, suspected of harboring endometrial cancer.** A diagnostic workup, at least an endometrial biopsy, but preferably an endometrial curettage, should be obtained without delay. **Cytology should not be used as a diagnostic weapon in obvious clinical situations unless a curettage cannot be performed.** However, **endometrial cancers may produce no symptoms whatever or only insignificant symptoms (such as discharge or spotting)** that are not readily elicited on routine questioning of the patient. **Such lesions may be discovered by cytologic techniques, and their diagnosis constitutes the chief application of cytology to the detection of endometrial cancer.**

CLASSIFICATION OF ENDOMETRIAL CARCINOMAS AND THEIR PRECURSORS

It is generally assumed that endometrial carcinoma is preceded by a series of molecular-genetic and morphologic modification of structure and configuration of endometrial epithelium and

glands. **Two pathways** of disease have been advocated (Sherman, 2000). For the common **endometrioid type of endometrial carcinoma**, the precursor lesion is known as **endometrial hyperplasia**. For the relatively uncommon **serous carcinoma**, the precursor lesion has been named **intraepithelial carcinoma**.

Histologic make-up of endometrial cancer may have considerable bearing on cytologic diagnosis because tumors of high grade with marked nuclear abnormalities are much easier to recognize than very well differentiated low grade tumors with relatively trivial nuclear changes. The classification of endometrial carcinomas and their precursor lesions, modified from the WHO classification (Scully et al, 1994), is shown below.

- **Endometrioid carcinoma**
- **Villoglandular carcinoma**
- **Endometrioid carcinoma with squamous differentiation (adenoacanthoma, adenosquamous carcinoma)**
- **Squamous carcinoma**
- **Precursor lesions of endometrioid carcinoma-endometrial hyperplasia**
- **Simple proliferative hyperplasia**
- **Atypical hyperplasia, carcinoma in situ (Hertig)**
- **Serous (papillary serous) carcinoma**
- **Intraepithelial carcinoma**
- **Rare type of carcinomas**

Endometrioid Carcinoma

Histology

As the name indicates, this malignant tumor is characterized by a **disorderly proliferation of the endometrial glands resulting in a grotesque image of the endometrium**. These tumors are usually **primary in the endometrium** but may also develop in **endometrial polyps** and in foci of **endometriosis** that may be located in a variety of primary sites, including the ovary and even the regional lymph nodes (Koss, 1963). The cancerous glands **vary in size and configuration**, are often **crowded**, and adjacent to each other without intervening endometrial stroma. Papillary projections into the lumen of the glands is not uncommon (Fig. 13-6A). The cancerous glands are lined by **cells that are larger than normal**, usually cuboidal but sometimes columnar (tall-cell carcinoma) in configuration. The nuclei of these cells vary from **simple enlargement and slight hyperchromasia** in low grade tumors to markedly **enlarged, sometimes hyperchromatic nuclei** in high grade tumors. **A characteristic feature of cells of endometrioid carcinoma is the presence of clearly visible nucleoli**. The number and size of the nucleoli also vary with tumor type, with one or two small nucleoli present in well differentiated tumors, when compared with up to four larger nucleoli in

P.431

high grade tumors (Long et al, 1958). The degree of nuclear abnormalities is the basis for nuclear grading that is thought to be of prognostic value. The frequency of mitotic figures varies.

Figure 13-6 Various histologic aspects of endometrioid carcinoma. A. Grade II adenocarcinoma. B. A cluster of large macrophages in the stroma of an adenocarcinoma. C. Another cluster of macrophages in the stroma of another endometrioid carcinoma. D. Adenoacanthoma.

The **stroma** separating the cancerous glands may occasionally show rather remarkable changes in the form of clusters of very **large macrophages**, first described by Dubs in 1923 (Fig. 13-6B,C). Rarely, concentric, often calcified protein secretions (**psammoma bodies**) may be formed by some of these tumors (Parkash and Carcangiu, 1997).

The degree of architectural differentiation of endometrial cancer may vary considerably and is of prognostic significance. Some tumors present only a **slight deviation from the normal endometrial pattern (grade I carcinomas, sometimes referred to as adenoma malignum)**; at the other extreme, there is a **grade III carcinoma**, presenting as a nearly **solid growth of cancer cells** in sheets with only an occasional attempt at gland formation. Most of the endometrial cancers fall somewhere between the two extremes and are graded II.

Villoglandular carcinoma is an uncommon variant of endometrioid carcinoma, characterized by formation of slender papillary fronds on the surface of the tumor (see Fig. 13-17B). The tumor cells are similar to those of a well-differentiated endometrioid cancer.

Endometrioid Carcinomas With Squamous Component (Adenoacanthomas and Adenosquamous Carcinomas)

In 25% to 40% of endometrial adenocarcinomas, depending on sampling, a squamous epithelial component may be observed. **The histologic appearance of the squamous component may vary from deceptively benign to frankly malignant** epidermoid or squamous cancer (Fig. 13-6D). The term **adenoacanthoma** has now been dismissed but I still find it useful in describing tumors with the histologically benign squamous component. The tumor type with malignant squamous component is usually classified as **adenosquamous carcinoma**. There is little doubt, however, that, regardless of its degree of differentiation and microscopic appearance, **the squamous component in adenoacanthomas is malignant and even capable of metastases**. We observed several cases in which the metastatic foci in the lungs were represented solely by the “benign” squamous component. The malignant nature of the squamous component has been confirmed by comparative genomic hybridization studies performed in this laboratory, that documented the presence of chromosomal abnormalities similar to those occurring in cancerous glands (Baloglu et al, 2000).

In fact, in our experience, **the occurrence of squamous “metaplasia” in material from endometrial curettings**

should always be viewed with suspicion, as it may represent fragments of low-grade adenoacanthoma. There is no known prognostic difference between endometrial

adenocarcinomas with or without the squamous component (Marcus, 1961; Pokoly, 1970), although an unfavorable prognosis has been recorded for patients with adenosquamous carcinoma treated by radiotherapy (Ng et al, 1973). Pure **squamous cancers of the endometrium may occur, though rarely**, and usually in older women (Peris et al, 1958; White et al, 1973; Houissa-Vuong et al, 2002).

Precursor Lesions of Endometrioid Carcinoma: Endometrial Hyperplasia

It is commonly thought that endometrioid carcinoma is preceded by precursor stages of endometrial carcinoma known as **endometrial hyperplasia** of various types.

Risk Factors

Hyperplasia, which occurs mainly in premenopausal women, is caused by a **hormonal imbalance** in favor of estrogens and may result from **disturbances of ovulation**, such as the **Stein-Leventhal syndrome**, in which the estrogenic phase is not followed by a progesterone phase. Hormone-producing ovarian tumors, such as **theca or granulosa cell tumors**, may also produce endometrial hyperplasia. Simple hyperplasia may also be **associated with leiomyomas** (Deligdisch and Loewenthal, 1970). In postmenopausal women, administration of unopposed exogenous estrogens is a known cause of hyperplasia (the Writing Group for the PEPI Trial, 1996).

Clinical Features

The essential clinical feature of endometrial hyperplasia, regardless of type, is a **period of amenorrhea followed by uterine bleeding that may be excessive in amount (menorrhagia) or irregular (metrorrhagia)**. In some patients, the bleeding may be fairly cyclic in character, whereas in others it is very irregularly spaced.

Histology

Although current textbooks and atlases of gynecologic pathology (e.g., Silverberg and Kurman, 1992) offer a variety of terms to describe various forms of endometrial hyperplasia, according to the configuration of the glands and the level of abnormalities in the epithelial lining, a simple classification is used here. **Three forms of endometrial hyperplasia** can be distinguished:

- Simple proliferative hyperplasia (endometrial hyperplasia with simple tubular glands without nuclear abnormalities)
- Cystic hyperplasia, which is probably a variant of simple hyperplasia
- Atypical hyperplasia (endometrial hyperplasia with nuclear abnormalities)

This classification disregards the configuration of the glands, but experience has shown that **in most hyperplasias with nuclear abnormalities, the endometrial glands are abnormally configured**.

Simple Proliferative Hyperplasia

Simple endometrial hyperplasia is an abnormality of endometrial growth in which the **equilibrium between the proliferative and the desquamative processes is disturbed in favor of the proliferative phase**. In this form of endometrial hyperplasia, the pattern of the endometrium is characterized primarily by an **increase in the number of tubular endometrial glands or their cross-sections per low-power field**. The glands are separated from each other by endometrial stroma. Often, the glands show slight **variability in size and irregular shapes** and thus differ from the normal, tubular proliferating glands, which appear round in cross-section (Fig. 13-7A,B). The **epithelial cells lining the hyperplastic glands** tend to pile up and are often arranged in a somewhat disorderly fashion (loss of polarity). Under high power of an optical microscope and, even more so, by scanning electron microscopy, **cilia are commonly observed on the surfaces of the endometrial glandular cells**, a feature normally associated with the estrogenic phase of endometrial proliferation (see Chapter 8). **Mitotic activity** may take place at all levels of the epithelium. The size of the nuclei reflects phases of the cell cycle. Most nuclei are of normal size. Occasionally, however, the nuclei are

slightly enlarged, reflecting late phases of cell cycle, and contain small nucleoli, changes that may also be observed in normal endometrium in proliferative phase.

Simple proliferative hyperplasias **do not show any chromosomal abnormalities by comparative genetic hybridization** and, therefore, must be considered as a benign disorder (Baloglu et al, 2000). These lesions are **polyclonal by molecular techniques, whereas malignant lesions are usually monoclonal** (Mutter et al, 2000).

Clinical Significance.

In many premenopausal women, the restoration of the ovulatory cycle by hormonal manipulation has resulted in the return to a normal endometrial pattern (the Writing Group for the PEPI Trial, 1996). Return to normal may also be expected after removal of estrogen-producing ovarian tumors. Yet, in rare cases, proliferative hyperplasia of long duration may become associated with atypical hyperplasia and endometrial carcinoma. Whether these are coexisting incidental events, as advocated by Horwitz et al (1981) or reflect some, as yet unknown, common pathway among these lesions, cannot be stated at this time.

Cystic Hyperplasia (Swiss Cheese Hyperplasia)

This disorder is seen mainly in peri- and postmenopausal women, although it may occasionally occur in premenopausal women. **The endometrial glands are of variable sizes but most are markedly dilated and cystic.** Their lumina are either empty or filled with amorphous material and debris. The epithelial lining of the glands is quite variable and may be separated into active and inactive forms. When the disease is observed **in premenopausal women, the gland lining is usually “active” and resembles that**

P.433

of simple proliferative hyperplasia, described above. In postmenopausal women, the gland lining is “inactive,” consisting of a single layer of cuboidal cells without any evidence of proliferative activity. In the latter situation, the disease must be differentiated from cystic atrophy of the endometrium (see Chap. 8).

Figure 13-7 Endometrial hyperplasia and Hertig's carcinoma in situ. *A, B.* Simple endometrial hyperplasia with cystic dilatation of glands. The epithelium of these glands is often ciliated. *C.* Complex (atypical) hyperplasia in which the glands are numerous, crowded, and of unequal size and irregular configuration. *D.* A form of atypical endometrial hyperplasia in which the glands form papillary projections lined by tall cells with eosinophilic cytoplasm. This lesion, named carcinoma in situ, was observed by Hertig et al (1949) in endometrial curettage specimens obtained some years before the development of an endometrioid carcinoma.

It is likely that cystic hyperplasia represents an end stage of involution of the simple proliferative

endometrial hyperplasia. The association of this form of hyperplasia with endometrial adenocarcinoma is uncommon, but I have repeatedly observed such lesions side by side.

Atypical Hyperplasia

Atypical or adenomatous hyperplasia is defined by an increase in the number of endometrial glands of various sizes and variable configuration per low-power field, usually associated with nuclear abnormalities in cells of the glandular epithelium (Fig. 13-7C). The atypical glands are separated from each other by endometrial stroma, although “back to back” glands, without intervening stroma, are also seen.

The epithelial cells in most of these lesions are similar to cancer cells because they are frequently enlarged, have enlarged nuclei with prominent nucleoli, and show intense mitotic activity at all levels of the epithelium. As in endometrioid carcinomas, the stroma may show accumulation of large macrophages.

In an important retrospective study by Hertig et al (1949), the precursors of endometrioid carcinoma were classified as **endometrial carcinoma in situ**, to be differentiated from the newly established entity, **endometrial intraepithelial carcinoma (EIC)**, the precursor lesion of the serous-papillary carcinoma. **Endometrial carcinoma in situ is a form of atypical hyperplasia** that was observed in prior endometrial biopsies and curettage material in women who subsequently developed endometrioid carcinomas. This lesion was characterized by endometrial glands of variable, irregular configuration, **lined with large, usually columnar cells with eosinophilic cytoplasm**, forming either single or multiple layers. Papillary proliferation and bridging of the lumen of the gland by proliferating epithelial cells may be observed. **The nuclei, which occupy variable positions in relation to the lumen, are enlarged, vesicular, and usually contain visible nucleoli.** The degree of cell abnormality is better appreciated if the gland lumen contains desquamated cells; these often show nuclear hyperchromasia and large nucleoli (Fig. 13-7D).

P.434

Comparative genomic hybridization disclosed that the atypical hyperplasia, even with trivial nuclear abnormalities, shares with endometrioid carcinoma a number of chromosomal abnormalities and, therefore, should be considered a precancerous lesion or an early stage of endometrioid carcinoma (Baloglu et al, 2000). It is not surprising, therefore, that in many instances the histologic differentiation of atypical hyperplasia from early carcinoma is a matter of dispute among competent pathologists. In fact, photographs of the two lesions in various publications could often be substituted for one another. One could repeat verbatim the statement regarding the differential diagnosis of precancerous lesions of the cervix, that “every debatable case could become a ‘shopping slide,’” ultimately handled by ablation of the uterus, not out of knowledge, but out of desperation. The famous saying “*kein Karzinom aber besser heraus*” (not a carcinoma but better take it out), attributable to a German gynecologist, Halban (cited by Novak, 1956), pertains to atypical hyperplasia. Some observers proposed the term **endometrial intraepithelial neoplasia (EIM), to encompass atypical hyperplasia and well differentiated endometrioid carcinomas** (Sherman and Brown, 1979; Fox and Buckley, 1982), a term that reflects the realities of the situation. The term has been revived recently by an Endometrial Collaborative Group that included 19 gynecologic pathologists from several countries by adding molecular biologic criteria (Mutter et al, 2000). **Monoclonality and instability of microsatellites, were the principal molecular abnormalities linking EIM to endometrial carcinoma.**

The relationship of simple proliferative hyperplasia to atypical hyperplasia is not clear and one cannot rule out the possibility that the benign form may sometimes be transformed into the malignant form.

The differential diagnosis of endometrial hyperplasia in curetted material includes endometrial polyps, artifacts produced by dull curettes, secretory endometrium in the premenstrual stage showing see-saw appearance of endometrial glands, and the glands of the endometrial basal layer, which are often somewhat dilated and irregular in shape.

Role of Hyperplasia in the Genesis of Endometrial Carcinoma

Evidence for progression of atypical hyperplasia to carcinoma of the endometrium is relatively poor because most of these lesions cause symptoms and are treated, at least by curettage and hormonal manipulation, but not infrequently by hysterectomy. At the time of this writing (2004), few patients with these abnormalities are left untreated. The evidence of progression is based on older studies. A frequently cited study is that by Gusberg and Kaplan (1963) in which a group of patients with "adenomatous hyperplasia" were prospectively followed; several of them (about 10%) developed endometrial cancer. Anecdotal evidence of progression of endometrial hyperplasia to carcinoma was also provided by Foster and Montgomery (1965). In a retrospective study of 170 patients, Kurman et al (1985) classified hyperplasias according to the degree of nuclear abnormality. Carcinoma developed in only 2 of 122 patients without significant cytologic atypia and in 11 of 48 women (23%) with "atypical" glands. The "progression" also depended on the complexity of the glandular pattern with "simple" lesions less likely to progress than "complex" lesions. Many of the lesions illustrated in the Kurman paper as "atypical complex hyperplasia" could be classified by other observers as a well-differentiated endometrioid carcinoma. Further, even though none of these patients were initially treated by hysterectomy, most received some form of treatment such as hormonal manipulation, curettage, or both. Hence, the rate of development of invasive cancer in untreated patients could be much higher.

However, **there is substantial evidence suggesting that endometrial hyperplasia is not a mandatory stage in the development of endometrioid carcinoma (or other types of endometrial cancer) that may also develop de novo, particularly in postmenopausal women.** The search for occult endometrial cancer (Koss et al, 1981, 1984) strongly suggested this possibility (see below). In an older contribution, Greene et al (1959) observed peripheral hyperplasia in only 10 of 120 cases of endometrial carcinomas. These authors expressed the view that, **"some (and probably the minority) of endometrial carcinomas are preceded by or possibly induced in or developed from areas of endometrial hyperplasia."** These observations are particularly valuable because they were published in 1959, before widespread use of hormones obscured endometrial pathology.

Based on a case control study, cited above, Horwitz and Feinstein (1978) proposed that **"endometrial hyperplasia and carcinoma may represent separate expressions of endometrial pathology, which may occur side by side, but do not necessarily follow each other. It is further suggested that the so-called atypical hyperplasia, a lesion most likely to 'progress' to invasive carcinoma, does in fact represent a low-grade endometrial carcinoma. The two lesions can only be separated from each other by a series of intricate and generally nonreproducible morphologic criteria."** Still, endometrial hyperplasia of whatever type must be construed as a warning sign that an endometrium is not cycling or not cycling properly and, therefore, is susceptible to neoplastic events. With luck and skill, the cytologic diagnosis of occult endometrial hyperplasia is sometimes possible either in cervicovaginal smears or in direct endometrial samples.

It has been reported that hormonal manipulation of atypical hyperplasia with progesterone and related drugs may occasionally restore the cycling endometrial pattern (the Writing Group for the PEPI Trial, 1996). Yet, in our experience, these drugs are rarely, if ever, curative of the disease. There is little doubt, however, that the presence of these abnormalities puts the untreated patient at risk for the development of endometrial carcinoma, although the degree of risk cannot be estimated in any individual patient.

Serous (Papillary Serous) Carcinoma

About 10% of endometrial cancers that are similar to ovarian tumors of comparable configuration have been recognized

P.435

many years ago as tumors with poor prognosis, capable of forming metastases, even if diagnosed in early stages (Chen et al, 1985). The tumors are composed of **large malignant cells, often forming papillary structures** that may contain **psammoma bodies** (Spjut et al, 1964; Factor, 1974). It must be stressed, however, that psammoma bodies may also occur in

endometrioid carcinoma, in benign endometria, and endometrial polyps in the absence of cancer. Quite often, the tumors infiltrate the myometrium as poorly formed glands or solid strands of tumor cells. **Mutation of p53 gene** occurs in the primary tumor and its metastases (Baergen et al, 2001).

Precursor Lesions of Serous Carcinoma

Recent studies of this group of tumors traced their origin to **malignant changes in the surface endometrium** and adjacent glands that has been labeled **endometrial intraepithelial carcinoma** (Fig.13-8A,B), and which is characterized by expression of **mutated protein p53** (Sherman et al, 1992, 1995, 2000). On the surface, the lesion is composed of a single or double layer of large cancer cells with large nuclei and nucleoli, sometimes in a palisade arrangement. Adjacent glands show similar changes. Mitotic activity is abundant. The proponents of EIC avoided the use of the term **endometrial carcinoma in situ**, an abnormality of **endometrial glands**, described by Hertig et al (1949) as a precursor lesion of endometrioid carcinoma, discussed above. It has been proposed that the genesis of serous endometrial carcinoma follows a different pathway from endometrioid carcinoma and is unrelated to endometrial hyperplasia (Sherman et al, 1992, 1995, 2000).

(*A,B:* courtesy of Dr. Robert Kurman, Johns Hopkins, Baltimore, MD.)

Rare Histologic Variants of Endometrial Carcinoma

Endometrial carcinomas may show evidence of secretory activity (**secretory carcinomas**) that may be a mucin-like substance (**mucinous carcinomas**). Such tumors should be differentiated from endocervical carcinoma. Some endometrial tumors are composed of “clear” cells, i.e., cells with transparent cytoplasm, showing cell arrangement not unlike that seen in similar tumors of the uterine cervix and vagina (**clear cell carcinomas; Fig. 13-8C**). Other rare types of endometrial cancer include **carcinomas with argyrophilic cells** (Ueda et al, 1979; Aguirre et al, 1984), **small cell (oat cell) type** (Paz et al, 1984), carcinoma with “**glassy cell features**” (Arends et al, 1984), **carcinoma with ciliated cells** (Hendrickson and Kempson, 1983; Gould et al, 1986; Maksem, 1997) and **carcinoma with giant cells**, resembling osteoclasts (Fig. 13-8D) (Jones et al, 1991).

P.436

Occasionally, endometrial carcinomas are composed in part of spindly malignant cells (**spindle cell carcinomas or carcinosarcomas**). The differential diagnosis of these tumors with

mesodermal mixed tumors is discussed in Chapter 17.

Staging and Prognosis

Endometrial carcinoma is staged according to the spread of the disease. In **stage I**, the disease is confined to the corpus, subdivided into **Ia** (depth of uterine canal less than 8 cm) and **Ib** (depth of uterine canal 8 cm or more). **Stage II** disease indicates involvement of corpus *and* cervix. **Stage III** indicates extension beyond the uterus but still confined within the bony pelvis, and **stage IV** indicates spread to the bladder and/or rectum, or evidence of distant metastases. Tambouret et al (2003) pointed out that extension of endometrial carcinoma to the uterine cervix may have a deceptively benign appearance in histologic sections. The role of **peritoneal washings** in staging of endometrial cancer is discussed in Chapter 16. Staging may also include **histologic grade (G) of the lesion**, discussed above, with G1 indicating a well-differentiated carcinoma, G3 poorly differentiated cancer, and G2 cancer of an intermediate grade. Poor prognosis of serous carcinoma, regardless of stage, has been mentioned above.

The results of treatment are by no means spectacular; only stage I G1 lesions respond well and offer a nearly 100% 5-year cure. For all stages and grades, the 5-year survival rate is only about 65%, and this figure has not changed much over the years (Frick et al, 1973; Prem et al, 1979; Robboy and Bradley, 1979; Partridge et al, 1996). More recent figures, based on a very large cohort of women in Norway, reported 5-year survival for all stages at 78% and 10-year survival at 67% (Abeler et al, 1992). The survival was stage dependent, with best results reported for stage I disease, and the poorest for stage IV. Hence, endometrial carcinoma is a serious, often misunderstood, disease and its early detection is a worthwhile undertaking.

Other Features of Prognostic Significance

Tumor Ploidy

DNA ploidy measurements have been shown to be of prognostic value in endometrial carcinoma (Atkin, 1984; Iverson and Laerum, 1985; Iverson and Utaaker, 1988; and others). It has been documented that tumors with approximately diploid DNA content have a better prognosis than aneuploid tumors. In general, well-differentiated endometrioid carcinomas have a diploid DNA content but occasionally higher grade tumors are also in the diploid range of measurements.

Morphometric Studies

Baak et al (1988) reported that combined architectural and nuclear morphometric features in tissue sections were a more accurate predictor of behavior of endometrial hyperplasia than nuclear features alone. This elaborate study requiring costly instrumentation and dedicated personnel is not likely to be of practical value in the laboratory.

Steroid Receptors

These studies have documented the presence of estrogen and progesterone receptors in most endometrial carcinomas and in some metastases (Ehrlich et al, 1981; Kauppila et al, 1982; Creasman et al, 1985; Utaaker et al, 1987). Lowerstage, better-differentiated tumors appear to have higher levels of both receptors and better prognosis than the receptornegative tumors. The presence of receptors in metastases may be used as a guide in hormonal manipulation and treatment of disseminated disease.

Molecular Studies

The presence of **mutated p53 protein** in serous carcinoma and, to a much lesser extent, in advanced endometrioid carcinomas, has been documented by Bur et al (1992) and by Sherman et al (1995). The presence of mutated p53 may be an expression of the documented poor prognosis of serous carcinoma. **Epidermal growth factor (EGF) expression** was extensively studied in endometrial cancer with conflicting results. While some investigators found the increased expression of this factor to be correlated with stage and grade of the disease (Battaglia et al, 1989), others failed to confirm these findings (Reynolds et al, 1990; Nyholm et al, 1993; Jassoni et al, 1994). It is of interest that Jassoni et al recorded the highest expression

of EGF in adenoacanthomas. Cell cycle regulators, such as **proteins related to the Rb gene**, are down-regulated in atypical hyperplasia and adenocarcinoma (Susini et al, 2001).

Molecular Genetic Studies

Baloglu et al (2001) have shown by the technique of comparative genetic hybridization that **chromosomal abnormalities are common in endometrioid carcinomas and in their squamous component**. Excess of chromosome 1 (at least triploidy), and gains and losses of chromosome 10, are the most common features, confirming direct cytogenetic observations. The reader is referred to the article cited for a detailed analysis of these abnormalities.

It has been documented that **endometrial cancers (and some atypical hyperplasias) are monoclonal in reference to chromosome X**, i.e., the tumors contain two X chromosomes, both of either maternal or paternal origin, whereas benign tissues and lesions are polyclonal, i.e., contain one chromosome each of maternal and paternal origin (summary in Mutter et al, 2000). It has also been observed that a subset of endometrial carcinomas show **microsatellite instability**, i.e., a change in the size of repetitive DNA sequences, known as microsatellites (Reisinger et al, 1993; Duggan et al, 1994). It remains to be seen whether these observations are of prognostic significance.

CYTOLOGIC PRESENTATION OF ENDOMETRIAL CARCINOMAS IN ROUTINE CERVICOVAGINAL SAMPLES

General Appearance

The **smears** from fully developed endometrial carcinomas are often characterized by the **presence of inflammation, necrotic material, and fresh and old (fibrinated) blood**

P.437

(Fig. 13-9). The latter may be observed in asymptomatic patients in the absence of clinical evidence of bleeding and may confer upon the smear a peculiar yellow-orange discoloration. The finding is more common in vaginal pool smears than in cervical samples. Such smears must be carefully screened for evidence of endometrial cancer, particularly in perimenopausal or postmenopausal patients. In **liquid samples**, this background **may be lost**.

Hormonal Pattern

In advanced cancer, the hormonal pattern is not distinctive and is of little diagnostic help, even though high maturation of squamous cells may be observed occasionally in a postmenopausal patient. Patients with **early stages of endometrial carcinoma are more likely to display excellent maturation of squamous cells** (Fig. 13-10A).

Recognition of Endometrial Cancer Cells

Endometrial cancer cells, usually accompanied by leukocytes and macrophages, **are often poorly preserved, concealed by blood and debris** and are difficult to identify under the scanning power of the microscope (see Fig. 13-9A). Therefore, the cytologic evidence of disease is often very scanty. The finding of endometrial cancer cells **in cervicovaginal smears** usually indicates the presence of **a fully developed endometrial carcinoma which may be occult**. When interrogated, most patients report a history of spotting.

Figure 13-9 Endometrial carcinoma in cervicovaginal smears. *A.* Low-power view of two clusters of endometrial cells against a background of marked inflammation. *B.* Higher power view of some of the inconspicuous small cancer cells (*arrows*) and macrophages. Note a mature squamous cell in the background. *C.* A cluster of cancer cells of various shapes and sizes. Some of the cells are cuboidal. The nuclear abnormalities consist of enlargement, coarse granulation, and the presence of nucleoli. *D.* Papillary endometrioid carcinoma corresponding to smears shown in *A-C*.

Cells of endometrial adenocarcinoma occur **singly and in clusters of various sizes**. Their **appearance varies in keeping with the degree of tumor differentiation**. Reagan and Ng (1973) used planimetry in the evaluation of cells of endometrial adenocarcinoma, and pointed out that the number of malignant cells in smears, the size of such cells, the size of their nuclei, and the degree of nucleolar abnormalities increase in proportion to the degree of histologic abnormality of the parent tumor. In our experience, high degrees of cytologic abnormalities in smears usually, though not always, correspond to fully invasive tumors.

Well-Differentiated Carcinomas

Single Cancer Cells

In such tumors, the single cancer cells are often **inconspicuous and small**, measuring from 10 to 20 μm in diameter

P.438

and, hence, are about the size of small parabasal squamous cells (see Figs. 13-9B,C and 13-10C). The cells are usually roughly **spherical, cuboidal or columnar**. Their **cytoplasm is bluish or slate gray in color, very delicate, and poorly outlined**. **Cytoplasmic vacuoles** are commonly present but vary in size and may be small and inconspicuous or occupy much of the cytoplasm. In the latter instance, the cells often assume the **signet-ring appearance** with the nucleus in eccentric position. Some of these cancer cells **resemble small macrophages**. As is common in mucus-producing tumor cells, the cytoplasmic vacuoles are sometimes **infiltrated with polymorphonuclear leukocytes** that may obscure the details of cell structure (Fig. 13-11C). **The nuclei are usually spherical, somewhat hyperchromatic, finely granular and often, but not always, contain small, but clearly visible nucleoli** (see Figs. 13-9C, 13-10B, 13-11A-C).

Figure 13-10 Endometrial adenocarcinoma in cervicovaginal smears. *A.* The smear pattern shows very high maturation of squamous cells. *B.* A cluster of endometrial cancer cells, one showing vacuolated cytoplasm and one showing nuclear enlargement. *C.* Numerous macrophages in a vaginal pool smear from the same patient. *D.* Endometrioid carcinoma grade II.

Cell Clusters

Well-differentiated endometrioid adenocarcinoma is easier to identify if the cancer cells occur in clusters. The clusters may be small and made up of only a few cells (Figs. 13-9C and 13-10B) or they may be larger. The clusters are often obscured by fresh or fibrinated blood and necrotic debris. The **cells forming the small clusters are often cuboidal or columnar in shape** and are characterized by somewhat granular spherical nuclei, usually provided with small but **clearly discernible nucleoli** (see Fig. 13-11B). Sometimes, the cancer cells form **rosette-like clusters** (see Fig. 13-11B). In larger clusters, which are sometimes of spherical (papillary) configuration, the small cancer cells are usually piled up, one on top of the other, and their identity may be difficult to establish.

The greatest **challenge** in cytology of well-differentiated endometrial carcinoma is the **identification and recognition** of endometrial origin of the often inconspicuous small cells, let alone their diagnostic significance. The **interpretation** of such preparations is often extremely difficult, particularly in the absence of symptoms.

In many such tumors, there are no detectable cytologic abnormalities at all and only **morphologically normal endometrial cells**, singly and in clusters, are observed. This finding is **particularly important in postmenopausal women**. In one of the very few papers dealing with cytology of **well differentiated (low-grade) endometrial carcinomas**, Gu et al (2001) observed that only 43% of 44 such patients had abnormal cervicovaginal samples, when compared with 72% (23 of 32) for high grade lesions (see below).

The **most important point of differential diagnosis** of clusters of endometrial cancer cells is **with atypical endocervical cells**. The endometrial cells are usually smaller than

P.439

endocervical cells and their cytoplasm is pale, scanty, and not sharply demarcated, whereas the cytoplasm of endocervical cells is usually more abundant and crisply outlined. Still, when the endometrial cells are of columnar shape, the distinction may be very difficult. Clinical history may help: endometrial cancer cells are most often encountered in perior postmenopausal women whereas the atypical endocervical cells occur mainly in younger age groups. Exceptions to these rules, however, occur quite often.

Figure 13-11 Occult endometrial adenocarcinoma diagnosed in cervicovaginal smears. *A.* A string of small cancer cells with hyperchromatic nuclei and very scanty cytoplasm against a background of high maturation of squamous cells. *B.* A cluster of very characteristic endometrial cells, some of columnar configuration, all showing enlarged granular nuclei, some containing nucleoli. *C.* Isolated poorly preserved endometrial cells, one with cytoplasm unfiltrated by neutrophiles. *D.* Asymptomatic endometrioid carcinoma, grade II, found in this patient.

High-Grade (Poorly Differentiated) Endometrial Carcinomas

Single Cells

Single cells of high-grade endometrioid carcinomas (and papillary-serous carcinomas, as emphasized by Wright et al, 1999) are much easier to recognize. The **cancer cells are large, measuring from 15 to 30 μm in diameter, and are usually provided with large, granular or homogeneous nuclei, often containing large, sometimes multiple nucleoli** (Fig. 13-12). Less often the nuclei are finely granular or even clear. **Enlarged and multiple nucleoli are an important diagnostic feature of the endometrial cancer cells in high grade tumors.** The nucleoli may not be visible in poorly preserved dark nuclei but usually stand out in better preserved cells. Long et al (1958) found a direct correlation between the number and the size of the nucleoli and tumor differentiation: In poorly differentiated tumors the number and the size of the nucleoli per nucleus were larger than in well-differentiated carcinomas.

The **cytoplasm** of the endometrial cancer cells is often distended by **vacuoles** of variable sizes. It may also be infiltrated with polymorphonuclear leukocytes. Sometimes, very bizarre cancer cells may be observed (Fig. 13-13A,B). The derivation of such cells may be difficult to establish.

Cell Clusters

In their most **conspicuous and classic form, the clusters are of oval or round papillary configuration and are made up of clearly malignant cells with scanty, frayed, basophilic cytoplasm and large, hyperchromatic nuclei** (Fig. 13-13C,D). The size of the component cells in clusters may vary and is related to the grade of the tumor. In relatively well-differentiated endometrial carcinomas, the cancer cells are generally smaller than in high-grade, poorly differentiated tumors. In all tumor grades, however, **conspicuous nuclear abnormalities are present: there is nuclear enlargement, nuclear hyperchromasia of varying degrees, and the presence of visible, occasionally large, sometimes multiple, and often irregularly shaped nucleoli.** The clusters are usually accompanied by single, classic

cancer cells elsewhere in the preparation. Similar clusters may reflect ovarian or tubal carcinomas (see Chap. 15).

P.440

Figure 13-12 High grade endometrial carcinoma in cervicovaginal smears. *A.* A cluster of large cancer cells at higher magnification to show markedly enlarged nuclei and irregular nucleoli. The smear background shows blood and mature squamous cells. *B.* High-grade, poorly differentiated tumor corresponding to *A.* *C.* Endometrial cancer cells showing large nuclei with prominent nucleoli and vacuolated cytoplasm, occasionally infiltrated by neutrophils. *D.* Endometrial carcinoma corresponding to *C.*

The presence of **psammoma bodies** in cases of endometrioid or serous carcinoma has been reported by Spjut et al (1964), Factor (1974), and Parkash and Carcangiu (1997). This finding is rare in cytologic preparations of carcinomas of the endometrium and much more common in ovarian cancer (see Chap. 15).

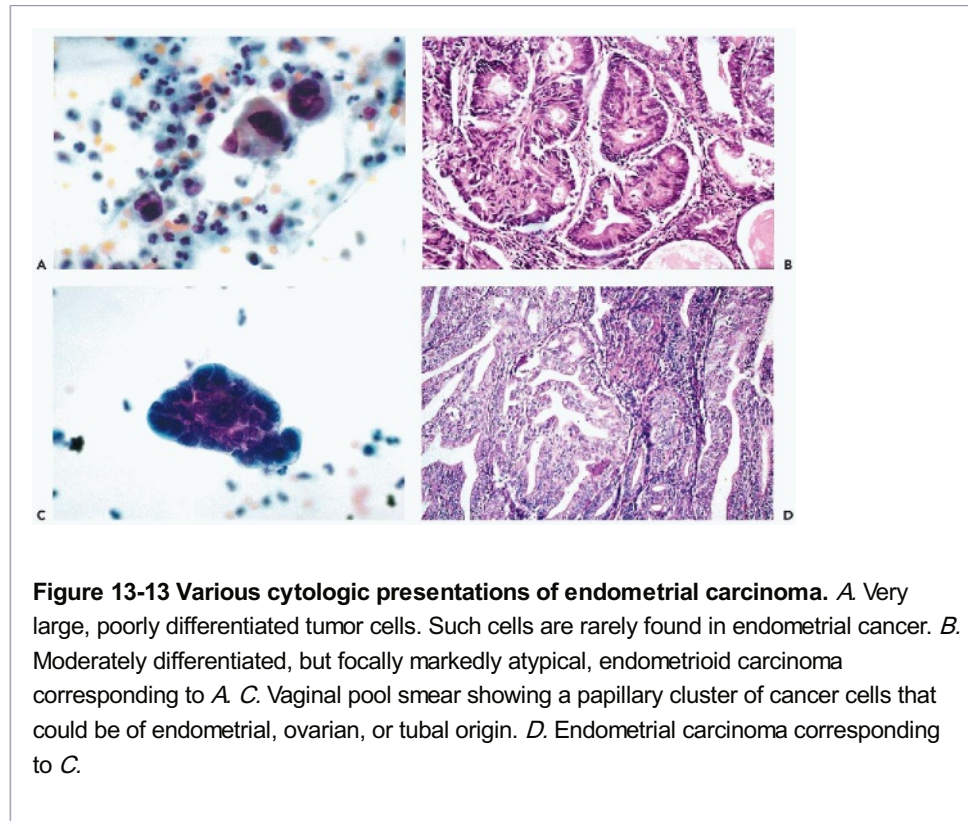

Macrophages (Histiocytes) in the Diagnosis of Endometrial Carcinoma

In our original contribution on the subject of endometrial carcinoma (Koss and Durfee, 1962), it was pointed out that, in **vaginal pool smears**, the presence of **macrophages (or of endometrial cancer cells mimicking macrophages)** is of help in the recognition of endometrial disease (Fig. 13-14). These observations were subsequently **re-examined** by various observers in **cervical smears** with negative results (Zucker et al, 1985; Nguyen et al, 1998; Tambouret et al, 2001). **We have repeatedly emphasized that the finding of macrophages in cervical smears is of no diagnostic value and that the negative results of these studies could be fully anticipated.** Still, **macrophages and macrophage-like cells** may accompany cells of endometrial adenocarcinoma but rarely tumor cells of other origins (see Figs. 13-11C and 13-14C). These cells have a delicately vacuolated cytoplasm and a round or kidney-shaped, occasionally eccentric nucleus. They may vary considerably in size. The origin of these cells appears to be endometrial stroma, which often contains islands of similar cells in histologic sections, as described above (see Fig. 13-6B,C). **Macrophages of this type may be, at times, the only evidence of endometrial cancer**, particularly in postmenopausal patients, **but are not diagnostic of this disease.** Still, their presence may lead the experienced observer to call for additional investigation of the endometrium. These observations were recently confirmed by Wen et al (2003). These authors reported that the presence of macrophages alone, in the absence of endometrial cells in cervicovaginal smears, led to the diagnosis of endometrial pathology (mainly polyps, but also carcinomas) in several patients.

Cells of Adenoacanthoma and Adenosquamous Carcinoma

It is sometimes possible to diagnose adenoacanthoma or adenosquamous carcinoma on cytologic evidence. In such

frankly malignant squamous cells (Figs. 13-15 and 13-16). Usually, the squamous cells **differ somewhat from cells of cervical squamous carcinoma**; their cytoplasm is sometimes **deeply keratinized**, and they tend to be **round or oval and lack the irregularity of shape seen in cervical cancer** (Fig. 13-15C). Buschmann et al (1974) referred to some such cells as “**keratin bodies**.” In extreme cases, fragments of keratin may be seen. The configuration of malignant squamous cells does not always provide a clue to the nature of the endometrial tumor. **Thus, squamous cancer cells may be observed either in adenosquamous carcinoma or in low grade adenoacanthoma.** The latter cases confirm the malignant nature of the seemingly benign “metaplastic” squamous component. Baloglu et al (2001) studied the foci of squamous differentiation in one such lesion by **comparative genomic hybridization and observed in it chromosomal abnormalities consistent with endometrioid carcinoma, thus confirming that the squamous component is an integral part of the malignant tumor.**

Rare Types of Endometrial Carcinomas

We have observed examples of superficial **villoglandular carcinoma**. The lesion shed papillary cell clusters composed of large cells with abundant eosinophilic cytoplasm and large, pale nuclei with visible nucleoli (Fig. 13-17A,B). We also observed a case of the very rare **clear cell carcinoma**. The large tumor cells with clear cytoplasm formed glandular structures, diagnostic of adenocarcinoma (Fig. 13-17C,D). The tumor type came as a surprise.

Praca et al (1998) described a case of the extremely rare **neuroendocrine small cell carcinoma** of the endometrium. The cytologic pattern of small malignant cells could not be distinguished from similar tumors of the uterine cervix.

Tumor Typing in Cytologic Samples

Although well-differentiated endometrioid carcinomas have a reasonably characteristic cytologic presentation, described above, **the precise histologic type of endometrial carcinoma can rarely be established in cytologic material.** High grade endometrioid carcinomas, their variants, and serous-papillary carcinomas shed similar cells.

When endometrial adenocarcinomas shed **papillary cell clusters**, the differential diagnosis must comprise **adenocarcinomas of the fallopian tube and ovary and adenocarcinomas**

of other origins metastatic to the female genital tract. If only single, large cancer cells are present in the

P.442

cytologic sample, the differential diagnosis should include other cancers, such as a poorly differentiated squamous (epidermoid) carcinoma and other poorly differentiated primary or metastatic tumors. Tissue evidence and immunohistochemistry may solve the problem in some, but not necessarily all, the cases.

Although the adenoacanthomas and adenosquamous carcinomas of the endometrium have a characteristic presentation, described above, they still have to be differentiated from coexisting endocervical adenocarcinoma and epidermoid carcinoma and adenosquamous carcinomas of the endocervix. The squamous component of all these lesions may be similar or identical but there is a difference in the configuration of the cells of endometrial and endocervical adenocarcinomas (see Chap. 12).

Efficacy of Cytologic Diagnosis

In our experience, about 65% of all cases of endometrial adenocarcinoma may be diagnosed in the now rarely used **vaginal smears** (Koss and Durfee, 1962). The **cervical smears** will yield a positive diagnosis in about 25% of cases. Nonetheless, the cytologic suggestion or diagnosis of endometrial carcinoma may be of diagnostic assistance if clinical symptoms of endometrial cancer are inadequately reported by the patient or improperly interpreted by the physician. In such patients, the cytologic diagnosis of endometrial carcinoma may come as a surprise to the clinical provider but requires further investigation with beneficial diagnostic and therapeutic results (Table 13-1).

The cytologic presentation of endometrial adenocarcinoma in direct endometrial samples is described below.

Pitfalls

- **Menstrual smears.** As repeatedly mentioned, endometrial cells and cell clusters may be found in cervicovaginal smears until the 12th day of the cycle, hence for several days after the cessation of the clinical bleeding. Therefore, one should **abstain from making the diagnosis of endometrial carcinoma in menstruating patients.**

- **Intrauterine contraceptive devices** may result in endometrial shedding, particularly at mid-cycle.
- **Effects of hormonal medication.** One of the most important pitfalls in evaluation of the endometrium in postmenopausal women is the effect of hormones. **All hormones**, whether estrogen, progesterone, androgens, or corticosteroids, **may stimulate endometrial growth** to varying degrees, resulting in **shedding of endometrial**

P.443

cells. If the pattern of the cervicovaginal smear is atrophic prior to therapy, any of these hormones but especially estrogens (and other **drugs, such as Tamoxifen and digitalis**), may produce improved maturation of the squamous cells (see Chap. 18). These effects have been observed by us even after administration of beauty creams with hormones. **Withdrawal bleeding**, particularly after the use of estrogens, may produce the perfect picture of endometrial carcinoma: high maturation of squamous cells, presence of endometrium and blood. Similar findings may be observed in women wearing IUDs (see above).

- In material from patients receiving **contraceptive hormones with high progestin content, single endocervical cells with enlarged, hyperchromatic nuclei, may appear**, rendering the differential diagnosis very difficult (see Chaps. 10 and 18). The only way to avoid the pitfalls of these iatrogenic situations is to obtain an accurate history of medications and to insist on histologic confirmation of any cytologic suspicion of endometrial carcinoma.
- **Endometrial polyps** may shed atypical endometrial cells that may be mistaken for cancer. Other disorders of endometrium that may mimic carcinoma are **chronic inflammatory processes**, particularly tuberculosis, **regenerating endometrium**, and **Arias-Stella cells** (see Chap. 8). Ehrman (1975) described two cases of postmenopausal women with cytologic findings suggestive of endometrial carcinoma, caused by atypical endometrial lining overlying **foci of stromal breakdown**. Ehrman pointed out that similar abnormalities may occur during normal menstrual bleeding and that the nuclei of endometrial epithelial cells may be very large and contain conspicuous nucleoli.

Figure 13-15 Endometrial adenoacanthoma in cervicovaginal smears in a 68-year-old woman. *A.* Endometrial cancer cells with vacuolated cytoplasm. *B.* A papillary rosette-like cluster of endometrial cancer cells. *C.* Endometrial cancer cells surrounding spherical, extremely well-differentiated squamous cells. *D.* Tissue section corresponding to *A-C* showing an endometrioid carcinoma with well-differentiated squamous component.

CYTOLOGIC DIAGNOSIS OF ENDOMETRIAL HYPERPLASIA IN ROUTINE CYTOLOGIC SAMPLES

Most patients with endometrial hyperplasia, regardless of type, are symptomatic and offer few opportunities for a cytologic diagnosis. Occasionally, however, there occurs an asymptomatic

(or minimally symptomatic) patient in whom the diagnosis of hyperplasia may be attempted in routine smears. Much of the confusion in the literature pertaining to the cytologic diagnosis of endometrial hyperplasia is caused by lack of correlation of the cytologic findings with histology. The findings differ according to the histologic patterns of the

P.444

lesions. The only feature that these disease states may have in common is the hormonal pattern in smears.

Figure 13-16 Endometrial adenoacanthoma. A. Two large papillary clusters of endometrial cancer cells. B, C. Isolated, well-differentiated squamous cancer cells in the same smear. D. Adenoacanthoma corresponding to A-C.

Hormonal Pattern

Premenopausal Women

Sequential vaginal smears in women with endometrial hyperplasia may show a fairly constant pattern of maturation of squamous cells *without the customary cyclic variations*. The maturation is not necessarily very high and may remain moderate for long periods of time. **The assessment of the hormonal status in a single cervicovaginal smear may be highly misleading.** Only multiple smears repeated over several cycles may provide this information (see Chap. 9).

Postmenopausal Women

In these patients, there is usually a pattern of good maturation of squamous epithelium. As has been emphasized before, **such findings in postmenopausal patients are not necessarily abnormal** and only a constant, very high level of maturation of squamous cells **in the absence of medication of any type** may be considered unusual.

Endometrial Cells

Simple Proliferative and Cystic Hyperplasia

In the rare asymptomatic patients with simple proliferative or cystic endometrial hyperplasia, there is limited spontaneous shedding of endometrial cells, except during episodes of bleeding. In routine cytologic preparations, the **cells shed from hyperplastic endometrial glands resemble normal endometrial cells in size and appearance**. Rarely, there is slight nuclear enlargement and hyperchromasia and small nucleoli can be visualized (see Fig. 10-18A,B). In several personally observed **premenopausal patients** who did not wear IUDs, the possibility of endometrial hyperplasia could be suggested because of the presence of morphologically normal endometrial cells past the 12th day of the cycle.

In **postmenopausal patients, the finding of endometrial cells in routine smears may indicate either a hyperplasia or a carcinoma, and the cytologic diagnosis of hyperplasia should not be attempted.** All such patients should be investigated by biopsy or curettage.

Atypical Hyperplasia

The cells shed from **atypical endometrial hyperplasia cannot be differentiated from cells of a well-differentiated endometrioid carcinoma, described above.** In several such personally observed cases, the diagnosis of atypical hyperplasia was established in histologic material and could be, as always, a matter for some dispute (Fig. 13-18C,D).

These observations were confirmed by Ng, Reagan, and Cechner (1973) who studied the cell patterns and features of endometrial cells in endocervical aspiration smears of 116 women with various forms of endometrial hyperplasia and

P.445

endometrial carcinoma in situ, as defined by Hertig et al (1949), and observed that the degree of cytologic abnormality was related to the severity of histologic abnormality.

Figure 13-17 Villoglandular and clear cell carcinomas. *A.* A large papillary cluster of well-differentiated endometrial cancer cells with large nucleoli. *B.* In the tissue section corresponding to *A*, the typical villoglandular pattern of an endometrial cancer. *C.* Papillary clusters of large cells with clear cytoplasm, large nuclei, and nucleoli, corresponding to the tissue section of a clear cell endometrial carcinoma shown in *D*.

Endometrial Lesions in Endocervical Brush Specimens

Although the endocervical brushes were not designed to sample the endometrium, vigorous brushing may reach the lower segments of the uterine cavity. As has been discussed in Chapter 8, benign endometrial cells may be found in such samples and constitute a known source of diagnostic error. **Occasionally, however, the endocervical sample contains evidence of an endometrial lesion.** An example of markedly atypical endometrial hyperplasia discovered in an endocervical brush specimen is shown in Figure 13-19.

TABLE 13-1 ENDOMETRIAL ADENOCARCINOMA IN SYMPTOMATIC PATIENTS: VAGINAL SMEARS ONLY

Total Cases	Positive	No Diagnosable Cancer
63 (100%)	40 (63.5%)*	23 (37.1%)

* In 8 cases, cytology contributed significantly to speedy diagnosis. (Koss LG, Durfee GR. Cytologic diagnosis of endometrial carcinoma. Result of ten years of experience. *Acta Cytol* 6:519-531, 1962.)

CYTOLOGY OF DIRECT ENDOMETRIAL SAMPLES

Instruments

Over the years, many instruments have been introduced for purposes of direct endometrial sampling. Some of the

P.446

instruments were to replace an endometrial biopsy or even curettage in symptomatic or "high-risk" patients. Other instruments were proposed as "screening" tools for the detection of occult carcinoma or hyperplasia. The goal of all these instruments was to secure an adequate sample of the endometrium, without causing much discomfort to the patient.

Figure 13-18 Endometrial hyperplasia and Hertig's carcinoma in situ. *A* A cluster of small endometrial cells corresponding to cystic hyperplasia shown in *B*. *C* A cluster of abnormal endometrial cells, one with large nucleus, corresponding to the classical Hertig's carcinoma in situ shown in *D*. The cells in *A* are benign in configuration. The cells in *C* could be classified as endometrial carcinoma.

The first such device, with which the writer had personal experience, was a simple endometrial aspiration cannula, introduced by the late Dr. Michael Jordan in the 1950s. The cannula was used as an office instrument on high-risk patients and led to the discovery of a number of occult endometrial hyperplasias and carcinomas (Jordan et al, 1956; also see below). Numerous sampling instruments were subsequently introduced, among them the endometrial brush (Johnsson and Stormby, 1968), Gravlee's negative-pressure jet wash (Gravlee, 1969), an endometrial "pistol" (Bouchardy et al, 1987), Mendhosa cannula (Jimenez-Ayala et al, 1975), Matsubuchi apparatus (Inoue et al, 1983) and others, listed in the bibliography. Two instruments, Isaacs' endometrial sampler and Mi-Mark cannula, were used by us in a large study of endometrial cancer detection in asymptomatic women (Koss et al, 1981, 1984). More recently, a number of thin, plastic sampling instruments were introduced, the Endopap Sampler (Bistoletti et al, 1988) and the Tao brush (Tao, 1993; Maksem and Knesel, 1995; Maksem, 2000). The instruments cause less discomfort to the patients. A number of newer small biopsy devices are currently on the market (for a detailed discussion of these devices see Mishell and Kaunitz, 1998) and appear to give satisfactory results with only a moderate degree of discomfort to the patients.

The initial testing of all these instruments was usually performed on symptomatic women, prior to endometrial biopsy or curettage. Not surprisingly, the initial reports usually presented the performance of the instrument in glowing terms, often claiming an accuracy of 100% or close to it, in the diagnosis of endometrial cancer and hyperplasia. On subsequent scrutiny, however, the performance was usually less successful and many of these instruments are no longer produced. The key issue, namely the discovery of asymptomatic endometrial cancer, was rarely addressed.

As an example, we had considerable experience with the **Gravlee Jet Wash**. The ingenious instrument was designed to obtain endometrial samples by washing the endometrium with a stream of normal saline, under negative pressure that prevented the fluid from entering the fallopian tubes or the peritoneal cavity (Kanbour et al, 1974). The fluid, containing endometrial fragments and cells, was centrifuged; the button was embedded in paraffin for histologic processing;

P.447

and the supernatant was examined by cytologic techniques. Initially, very high accuracy in the diagnosis of endometrial carcinoma was recorded by So-Bosita et al (1970), Bibbo et al (1974), and Lukeman (1974). However, when this technique was applied to a group of 303 unselected consecutive patients by Rodriques et al (1974), there was a substantial failure rate in the diagnosis of endometrial carcinoma (4 out of 8 cases) and an even higher failure rate for various forms of endometrial hyperplasia. Only advanced, symptomatic endometrial cancers with friable tissue could be diagnosed by this method. The jet of saline was apparently unable to remove sufficient diagnostic material from cohesive target tissue. To our knowledge, the cumbersome method is no longer used.

Figure 13-19 Atypical endometrial hyperplasia recognized in an endocervical brush specimen. *A,B.* Clusters of endometrial cells with markedly enlarged nuclei and nucleoli.

The original diagnosis on the smear was that of an endometrial carcinoma. *C,D.* The tissue lesion corresponding to the cytology shown in *A* and *B* shows markedly atypical hyperplastic glands (complex hyperplasia). There was no conclusive evidence of endometrial carcinoma.

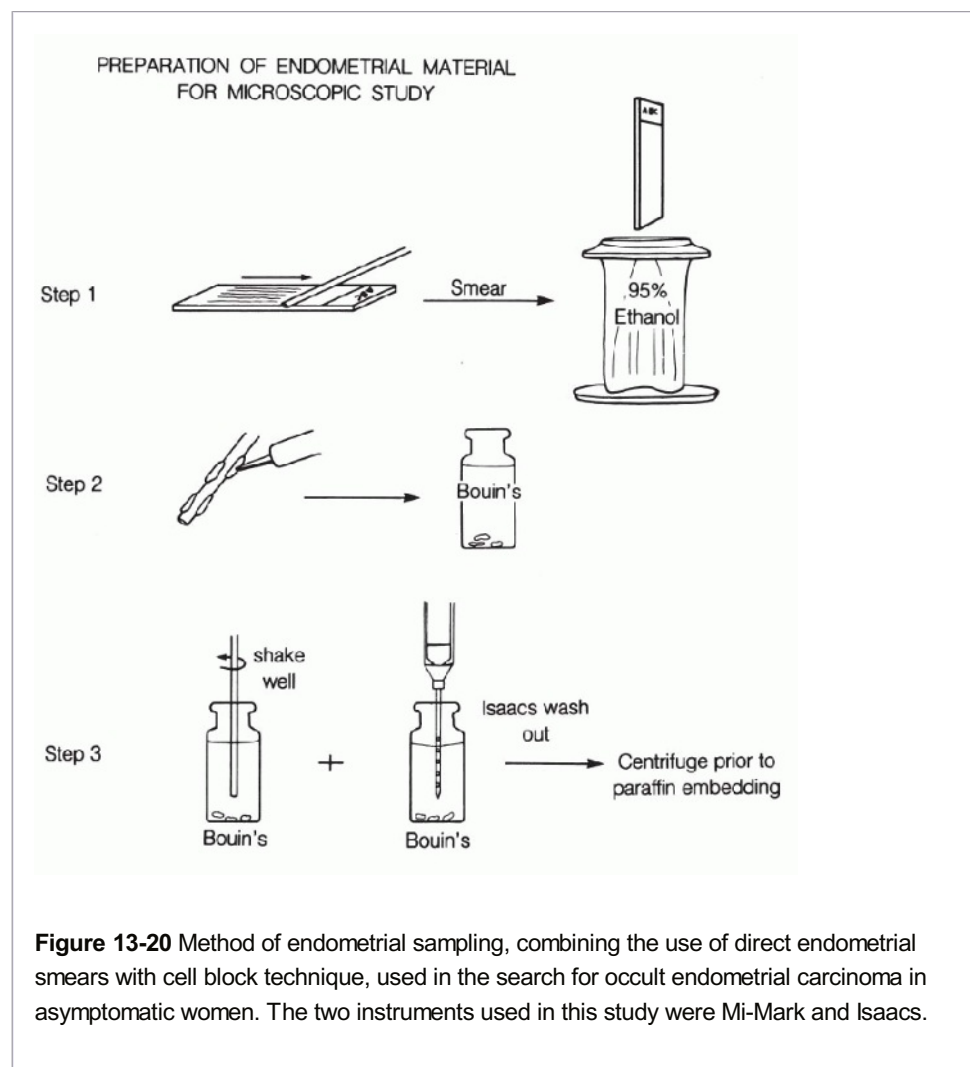

The **processing** of the endometrial samples can be performed either by **direct endometrial smears**, by the **cell block technique**, or by a combination of the two methods. Maksem and Knesel (1995) advocated the **collection of the endometrial samples in a liquid fixative** (CytoRich Fixative System, TriPath Inc) and processing of the sediment in a Hettich cytocentrifuge.

The direct endometrial smears are much easier and faster to prepare than cell blocks **but more difficult to interpret. The interpretation of the tissue patterns in cell blocks or microbiopsies** is much easier, although the preparation is time-consuming.

We had extensive experience with the cell block technique, beginning in the 1960s, when the late Dr. Virginia Pierce and this writer conceived of a histologic method of investigation of the endometrium. The procedure, based on a **simple suction-aspiration of the endometrium via a cannula**, was well tolerated by patients, and resulted in small tissue fragments processed by the cell block technique. The method, applied to several hundred patients, gave excellent quality of preparations, was very rapid, and resulted in a number of important, sometimes unsuspected diagnoses.

The **Mi-Mark and Isaacs instruments** were used in the search for occult carcinoma in a large cohort of asymptomatic women (see below). A **combination of direct smears and cell blocks** was used. The **procedure** was as follows: after preparation of a direct smear, the material still attached to the sampler was first carefully retrieved with a thin forceps; additional fragments were retrieved by shaking and washing the instrument in **Bouin's fixative**, prior to processing as cell blocks. Bouin's fixative was selected as offering the optimal preservation of the tissue fragments. Multiple sections of the cell block must be examined. The combination of the two procedures, admittedly time-consuming and costly, gave satisfactory results. A diagram of the procedure is shown in Figure 13-20.

P.448

Interpretation

Adequacy of Samples

Except in women with complete atrophy of the endometrium (usually past the age of 55), the smears should contain at least five or six clusters of endometrial epithelial cells to be judged adequate.

Composition of Smears

The summary of cytologic findings that follows is a composite of the early experience with several hundred samples obtained with Jordan's cannula prior to 1970 and on data from over 4,000 direct endometrial smears examined in the 1980s during the search for occult endometrial carcinoma and hyperplasia, described below. Some material, processed by liquid fixation in CytoRich and centrifugation, graciously made available by Dr. John Maksem from Mercy Hospital Medical Center, Des Moines, Iowa, was also included in the review. The analysis of direct endometrial samples is facilitated by **accurate clinical information, including the age of the patient, obstetrical and menstrual history and clinical symptoms, if any.**

Key Features

The interpretation of the microscopic findings requires knowledge of the many aspects of benign endometrial cytology and sources of error.

The key features that should be investigated are:

- **Number and cellular make-up of epithelial clusters**
- **Cohesiveness of epithelial cell clusters**
- **Nuclear abnormalities**, mainly enlargement and the presence of **readily visible nucleoli** in endometrial epithelial cells

Cycling Endometrium

Except in the presence of marked inflammation or a necrotic carcinoma, the smears usually have a clean background. Blood is invariably present, unless eliminated by processing. In menstruating women, the endometrial samples usually contain **numerous clusters of epithelial and stromal cells.**

Benign epithelial glandular cells, derived from the superficial layers of the endometrial lining and adjacent glands, **appear mainly as flat, cohesive "honeycomb" type of sheets, wherein cell borders can be clearly seen, or as three-dimensional, tubular structures, reflecting endometrial glands** (Fig. 13-21A,B). In the flat clusters, **the nuclei, measuring about 7 to 8 μ m in diameter, comparable in size to the nuclei of parabasal squamous cells, are open (vesicular) and sometimes faintly granular.** The appearance of the epithelial cells and their nuclei varies somewhat with the phase of the menstrual cycle.

In the proliferative phase, the epithelial cells have scanty, basophilic cytoplasm. There is some **variability of nuclear sizes**, accounted for by various stages of cell cycle in proliferating cells. Tiny, single **nucleoli** and occasional **mitotic figures** can be observed (Fig. 13-21B). In some cases, there is a **breakdown of clusters**, probably an artifact of smear preparation: in the dispersed cells, the variability of nuclear sizes can be better appreciated. Exceptionally, **ciliated glandular cells** can be observed. Their provenance from the endometrium or the endocervix cannot be ascertained.

P.449

Figure 13-21 Normal endometrium in direct endometrial samples. A. Normal endometrial tubular glands. B. A sheet of endometrial cells in proliferative phase. The cells form a cohesive cluster wherein mitoses may be noted (*arrow*). C. Loosely structured cluster of endometrial cells with vacuolated cytoplasm, corresponding to the secretory phase. D. Atrophic endometrium. The sheet of endometrial cells shows spacing between nuclei, characteristic of atrophy.

In the **early secretory phase**, the epithelial cells are usually larger because of increased volume of cytoplasm that is often vacuolated. At the edge of cell clusters, columnar cells with clear cytoplasm may be observed (Fig. 13-21C). Similar features may be observed in dispersed cells. The **nuclei** are usually **monotonous in size** and do not show either nucleoli or mitotic activity. In **late secretory endometrium**, the endometrial cells usually occur in **thick clusters**, sometimes in tubular or glandular configuration. At the periphery of the clusters, columnar epithelial cells with clear cytoplasm may resemble endocervical cells.

Endometrial Stromal Cells

In menstruating women, regardless of the stage of cell cycle, or in proliferating endometrium from whatever cause, the **stromal cells** appear in the background as **numerous, small, spindly “naked” nuclei**, sometimes surrounded by a very narrow rim of cytoplasm. In late secretory endometrium or under the influence of hormones, the stromal cells may become **larger, with a more abundant cytoplasm, reflecting decidual changes** that may occur under such circumstances. Tao (1995) reported that the configuration of stromal cells is helpful in assessing the stage of the menstrual cycle but, in my experience, this feature is difficult to assess.

Timing of Ovulation

Although differences could be observed between proliferative and secretory endometria, it has been our judgment that direct endometrial cytologic samples are **not** the proper tool for timing of ovulation. Endometrial biopsies, study of endocervical mucus, body temperature, and hormonal determination, as described in Chapter 9, are easier to interpret and better-suited methods for this purpose. It must be mentioned that Tao (1995) reported adequate results of endometrial dating, using his instrument, the Tao brush.

Atrophic Endometrium

In **postmenopausal women with endometrial atrophy**, the **number of clusters of epithelial cells is small**, sometimes limited to three or four small clusters. In smears of this type, the endometrial epithelial cells usually form **flat, well-spread clusters**, wherein the cells show a distinct honeycomb-type arrangement. The epithelial cells and their nuclei are generally smaller than those in the proliferative or secretory endometrium (Fig. 13-21D). The **stromal cells** are sparse. **Mono- and multinucleated macrophages** are occasionally observed in

such smears (see Chap. 8). Changes in the cytologic pattern in this group of women should always suggest the possibility of a neoplastic disorder and warrant careful scrutiny of such material (see below).

P.450

Endometrial Adenocarcinoma

The diagnosis of endometrial carcinoma in direct endometrial samples can be established by the presence of **enlarged endometrial epithelial (glandular) cells with enlarged nuclei, wherein reside clearly visible large, usually single, nucleoli**. The cytoplasm is usually scanty, basophilic, and sometimes vacuolated. The cancer cells may **be dispersed and occur singly** or may form **clusters**, that are either **flat or multilayered**, the latter of **papillary configuration**. The **flat clusters** are usually **loosely structured, sometimes forming "rosettes," often with detached cancer cells at their periphery**. The **multilayered clusters appear as dark, oval, spherical or irregular structures that are, per se, abnormal**, even if their cellular make-up may be difficult to study, except at their periphery. By comparing cytologic findings with endometrial tissue samples, it could be documented that similar cells are found in the lumens of cancerous glands (Figs. 13-22, 13-23 and 13-24).

Nuclear Abnormalities

As mentioned above, the most conspicuous nuclear changes are **nuclear enlargement, hyperchromasia, and the presence of large nucleoli**. In some cases, however, there is the **absence of nuclear hyperchromasia, resulting in granular, pale nuclei with visible nucleoli**, that stand out as pink dots that vary in size and configuration, ranging from small and spherical to large and irregular, the latter usually seen in high grade cancers (Fig. 13-22B).

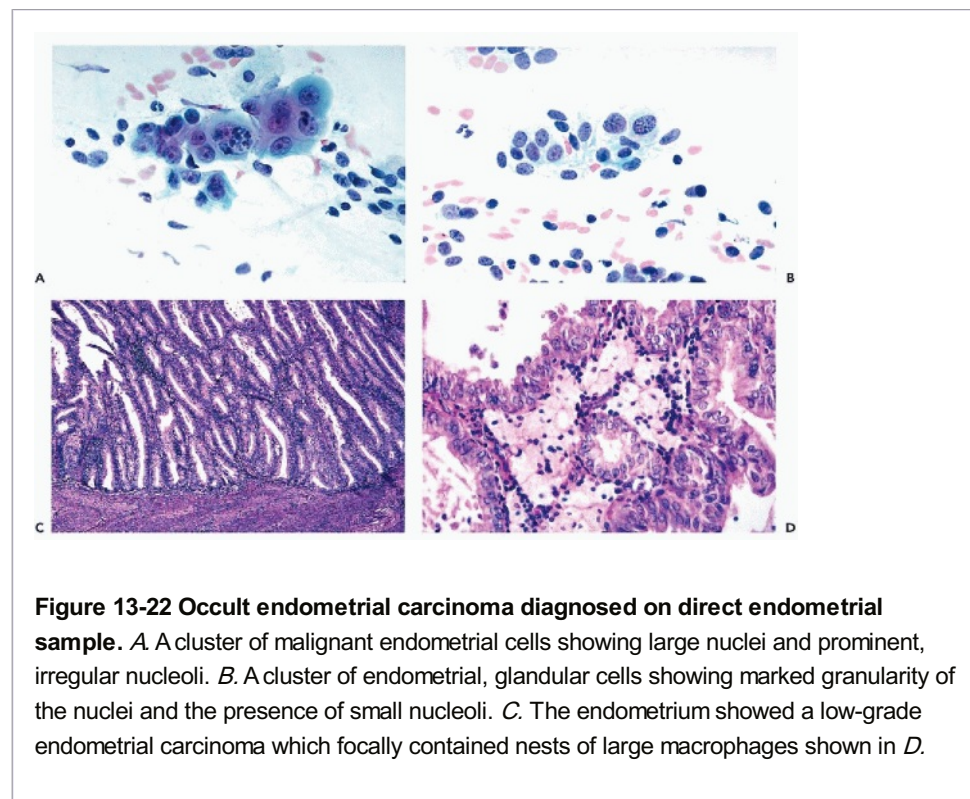

Figure 13-22 Occult endometrial carcinoma diagnosed on direct endometrial sample. *A* A cluster of malignant endometrial cells showing large nuclei and prominent, irregular nucleoli. *B* A cluster of endometrial, glandular cells showing marked granularity of the nuclei and the presence of small nucleoli. *C* The endometrium showed a low-grade endometrial carcinoma which focally contained nests of large macrophages shown in *D*.

In high grade carcinomas, the nuclear abnormalities are conspicuous (Fig. 13-24). However, during the extensive search for occult endometrial carcinoma, it became evident that, **in some cases of endometrial cancer, the nuclear enlargement is only slight and the nucleoli are small** (Fig. 13-23C,D). Yet, subsequent histologic evidence has shown that all or nearly all of the minimally abnormal cells had to be derived from cancerous endometrium that was lining the entire surface of the endometrial cavity.

Nuclear Grading

In 1995, Zaino et al introduced the concept of nuclear grading as a prognostic factor in endometrioid adenocarcinoma. Small, spherical nuclei were graded as I, whereas large, irregularly shaped nuclei with large nucleoli were graded III, grade II being intermediate between the two. Maksem (2000) applied the system to direct endometrial samples. However, the results of the study were not completely convincing because high grade nuclear abnormalities were occasionally observed in the absence of documented

P.451

cancer, possibly representing small foci of endometrial atypia that escaped histologic scrutiny. The clinical significance of Maksem's observations is unknown at this time.

Figure 13-23 Occult endometrial adenocarcinomas discovered on direct sampling.

A. A papillary cluster of endometrial cancer cells with enlarged nuclei, visible nucleoli, and vacuolated cytoplasm. Next to this cluster, there is a sheet of spindly endometrial stromal cells. Note the difference in nuclear sizes. *B.* Well-differentiated endometrial adenocarcinoma corresponding to *A*. *C.* A cluster of inconspicuous endometrial cancer cells showing only slight deviation from normal. The nuclei are somewhat enlarged and granular, containing tiny nucleoli. *D.* Section of well-differentiated endometrial carcinoma corresponding to *C*.

Unusual Findings

Occasionally, the **endometrial cancer cells are mixed with atypical squamous cells**, leading to a diagnosis of an **adenoacanthoma**. In such cases, it is important to rule out a cervical lesion of a similar cellular make-up (see Chap. 11). Unusual findings include **ciliated carcinoma and endometrial intraepithelial carcinoma**, both described by Maksem (1997, 1998). Infiltration of cancer cells by polymorphonuclear leukocytes may be conspicuous (see Figs. 13-24C and 13-27C).

Diagnosis of Endometrial Carcinoma in Various Age Groups

In **menstruating women**, the diagnosis of endometrial carcinoma in direct endometrial samples is **difficult** because the evidence may be scanty and may be obscured by a large number of clusters of benign endometrial epithelial cells.

The **diagnosis is easier in postmenopausal women**. Endometrial cancer cells, singly or in clusters, as described above, **are much easier to recognize against the sparse cellular background**. In the extensive search for occult endometrial carcinoma (see below), it became evident that the **mere presence of abundant clusters or sheets of endometrial cells in a postmenopausal woman was an important warning sign of possible pathologic changes, even in the absence of conspicuous nuclear abnormalities**.

Endometrial Hyperplasia

The recognition of endometrial hyperplasia in direct endometrial smears is fraught with difficulty. This was recognized already during the early experience with Jordan's cannula and enhanced still further during the search for endometrial abnormalities in asymptomatic women. As a general rule, the endometrial samples in hyperplasia are **rich in cells and cell clusters**. This finding is **significant only in postmenopausal women** in whom, in my experience, hyperplasia is a relatively uncommon finding **and cannot be differentiated from a carcinoma**.

It is virtually impossible to establish the diagnosis of **proliferative, simple hyperplasia in endometrial samples**. The

P.452

pattern of smears is that of benign endometrium, occasionally with a slight nuclear enlargement and some evidence of mitotic activity in epithelial cells. The recognition of **atypical hyperplasia** is almost equally difficult in either premenopausal or postmenopausal patients. The only finding of note, observed several times in the large endometrial study, was **cohesive sheets of epithelial endometrial cells with moderately enlarged nucleoli** (Fig. 13-25A,B). The differentiation of such clusters from a well-differentiated carcinoma (or **endometrial polyps** that may have an identical presentation) is impossible on cytologic grounds alone. The difficulty persists, even if the cytologic samples are supplemented by cell blocks. Occasionally, the diagnosis **cannot be proved**, either on biopsies or curettages, even after extensive follow-up (Fig. 13-25C,D). Such findings may represent transient or tiny abnormalities of the endometrium.

Figure 13-24 Occult serous endometrial adenocarcinoma diagnosed in direct endometrial sample. A,B. Large clusters of endometrial cancer cells with markedly enlarged nuclei and prominent nucleoli. **C.** Cancer cells with cytoplasm densely infiltrated by polyps. **D.** Fragment of endometrial papillary serous carcinoma corresponding to A-C.

Our difficulties with the diagnosis of endometrial hyperplasia are by no means unique. Thus, Meisels and Jolicoeur (1985), using a device known as the "Endo-pap" endometrial sampler, diagnosed only one half of 207 cases of hyperplasia using a number of complex criteria. Unfortunately, their paper failed to address the issues of type of hyperplasia and the clinical setting in which the diagnosis was established (symptoms and age of patients). In a large review of endometrial cytology, Mencaglia (1987) also admitted a large number of failures in the cytologic diagnosis of hyperplasia.

Sources of Error in Direct Endometrial Samples: Endocervical Cells vs. Endometrial Cells

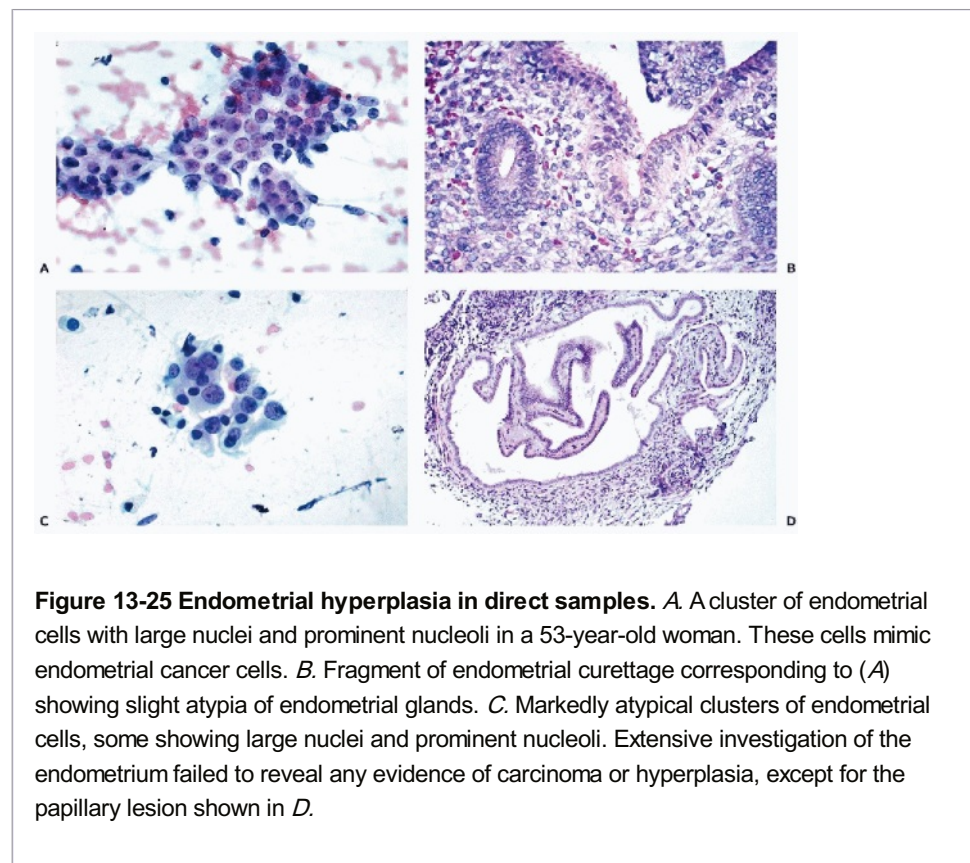

The most important **source of diagnostic difficulty in direct endometrial samples is the**

separation of endometrial from endocervical cells. In our own studies, numerous endometrial biopsies were obtained, based on a mistaken belief that the atypical endocervical cells represented an endometrial lesion. In general, the **endocervical cells are larger and have more abundant, sharply demarcated cytoplasm** than endometrial cells. A nuclear protrusion (nipple) often found in endocervical cells at midcycle (see Chap. 8) has not been observed by us in endometrial cancer cells although such changes may be observed in normal endometrium.

The difficulties are compounded if the endocervical cells in the endometrial samples show abnormalities such as large nucleoli that may be present in acute or chronic cervicitis and in florid metaplasia or repair. The latter may be caused by an endometrial or endocervical polyp and may be readily confused with endometrial carcinomas. Occasionally, **chronic cervicitis with papillary configuration of epithelium (papillary endocervicitis)** may shed cell fragments mimicking papillary endometrial carcinoma (Fig. 13-26). Another feature of

P.453

endocervical cells, namely the presence of occasional **enlarged, hyperchromatic nuclei (karyomegaly)**, such as observed in the presence of **CIN** or **endocervical adenocarcinoma** (see Chaps. 11 and 12), may also be mistaken for an endometrial process.

OCCULT ENDOMETRIAL CARCINOMA

As yet, no method of screening for endometrial carcinoma has been devised, combining the ease of application with low cost and high reliability, comparable to the cytologic screening for precancerous lesions of the uterine cervix. Routine cytologic examination of **vaginal pool smears**, as originally advocated by Papanicolaou, serves a very useful purpose in this regard as discussed below. Regrettably, the method has been abandoned as a routine procedure because its efficiency in the diagnosis of cervical lesions is low. It must be stressed that **routine cervical smears are essentially useless for endometrial cancer detection**, except in the rare cases of fully developed cancers in asymptomatic women, usually because of stenosis of the cervical canal. As has been stated above, **endocervical brush specimens** may occasionally provide evidence of an endometrial lesion.

Vaginal Pool Smears

The **vaginal pool smears, obtained by a glass pipette or another instrument**, are very easy to obtain with no discomfort to the patients. **In our judgment, a properly obtained and fixed vaginal smear should be part of every gynecologic examination in all women past the age of 50 and in those younger women whose history or symptomatology may suggest an endometrial abnormality.** The search for asymptomatic endometrial carcinoma is facilitated in **vaginal smears** if the following categories of patients are scrutinized with particular care:

- Smears of postmenopausal patients with high maturation of squamous cells of unexplained etiology
- Smears of any patient in the fifth decade of life or older who has a history of abnormal bleeding or staining, or microscopic evidence thereof
- Smears displaying evidence of marked necrosis and containing macrophages in menopausal or postmenopausal patients. **It must be stressed, once again, that the presence**

P.454

of macrophages in cervical smears has no bearing on the status of the endometrium.

Figure 13-26 Clusters of endocervical cells from a case of papillary cervicitis, mimicking endometrial carcinoma. A,B. A dense cluster of glandular cells (*A*) which, on close inspection (*B*), shows columnar cells at the periphery. *C.* The corresponding tissue lesion showing papillary cervicitis.

The cytologic presentation of asymptomatic endometrial carcinoma is usually inconspicuous and calls for a systematic, often tedious and time-consuming search of the vaginal smear **for endometrial cells, regardless of morphologic appearance. The background of vaginal smears** is sometimes free of blood and debris. More commonly, fresh blood and/or amorphous, yellow-orange (in Papanicolaou stain) areas of old fibrinated blood may be observed. There is frequently **excellent maturation of squamous cells, regardless of menopausal status or time of cycle.**

The **endometrial cancer cells** in asymptomatic endometrial carcinoma **in vaginal smears** are usually **small, inconspicuous, and sometimes only slightly larger than normal endometrial cells** (Fig. 13-27). There are **three cytoplasmic features** that may assist in the identification of such cells:

- **Columnar shape** of small endometrial cells is observed in lesions of the lower uterine segment, although most such cells are approximately spherical or cuboidal
- The presence of **cytoplasmic vacuoles**

- The **infiltration of the cytoplasm by polymorphonuclear leukocytes**. This feature is not specific and may also be observed in degenerating, mucus-producing benign cells of either endocervical or endometrial origin, but it should trigger further investigation.

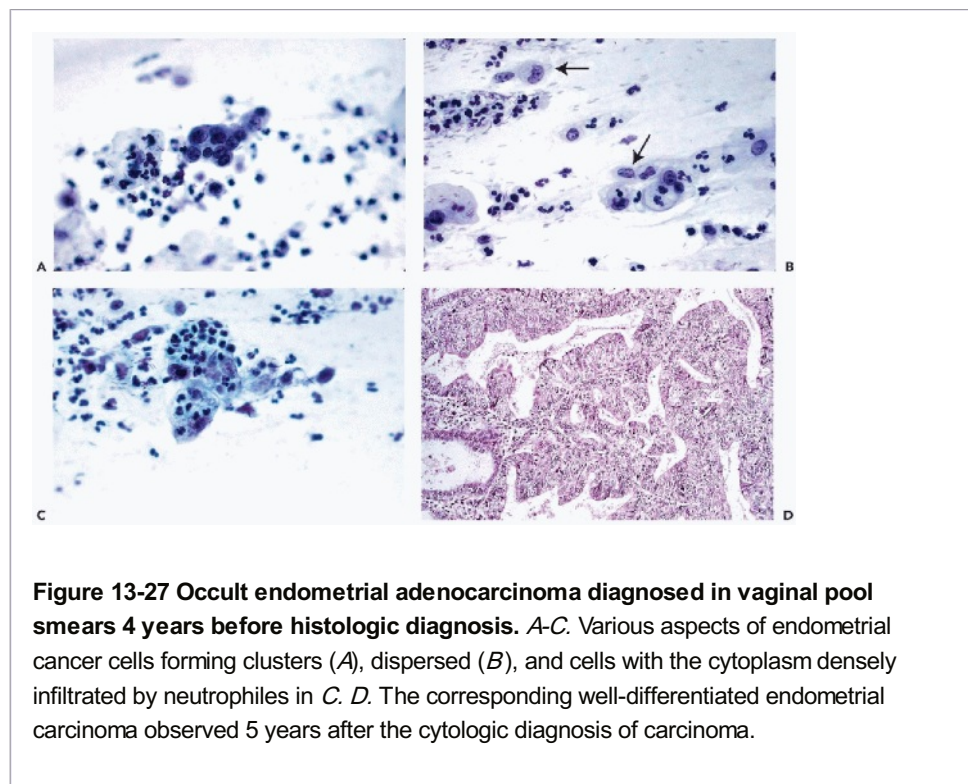

The **nuclei of the small endometrial cancer cells are larger than the nuclei of the parabasal or intermediate squamous cells** usually present in the field. They are generally finely granular and provided with conspicuous, although not necessarily very large single nucleoli. Rarely, the nuclei are **hyperchromatic and provided with large nucleoli**, usually reflecting the presence of a high grade tumor. Inadequate clinical follow-up of such patients may result in advanced cancer diagnosed at a later date.

The endometrial cancer cells are easier to identify when occurring in **clusters** that are usually small and rarely made up of more than a dozen cells. The clusters may be **flat, sometimes forming small rosette-like structures, or are multilayered, irregular or papillary** in configuration. The cells in clusters are usually round or oval, have a clear, sometimes vacuolated cytoplasm, and relatively **large, opaque, finely granular or somewhat hyperchromatic nuclei and often small nucleoli**. Sometimes, the manner of cluster formation of endometrial cancer cells closely resembles normal endometrium.

It must be emphasized that, in early endometrial carcinoma, **the shedding of cancer cells may be intermittent** and that a negative smear may immediately follow a positive smear and vice versa. **Thus, it is important to insist on further clarification of any abnormal cytologic finding, by endometrial biopsy or curettage, risking at times a false alarm.** It is equally important to insist on long-term follow-up if histologic confirmation of carcinoma

P.455

is not immediately forthcoming (Fig. 13-27). **Special care must be exercised in patients with stenosis of the endocervical canal in whom an endometrial biopsy may be difficult or impossible to obtain as an office procedure.**

Results

Table 13-2 summarizes the relationship of clinical symptomatology to histologic lesions in 102 cases of endometrial adenocarcinoma reported by Koss and Durfee in 1962. The diagnosis in all of the 22 asymptomatic patients and in 17 patients with slight symptoms (such as brownish discharge or history of spotting but no frank bleeding), a total of 39 cases, was made by

vaginal pool smear cytology and subsequently confirmed by histology. In this study, 12 of the 22 patients with asymptomatic endometrial carcinoma were still menstruating; their average age was 6 years less than that of fully symptomatic patients. The latter findings are summarized in Table 13-3. It may be noted that not all of the patients with early lesions were asymptomatic and not all of the patients with advanced lesions were symptomatic. Among the asymptomatic patients there were also several invasive endometrioid cancers. It must be noted that, in three patients, a major delay in clinical diagnosis occurred. At the time of histologic diagnosis, advanced carcinoma was present (see Fig. 13-27). This experience, repeatedly confirmed since the publication of this paper, points out that the evolution of endometrial carcinoma is slow in many cases, offering ample opportunity to diagnose the disease in its early stages.

Endometrial Minibiopsies (Cell Block Technique)

The method of endometrial investigation that was conceived in the 1960s by Dr. Virginia Pierce and this writer to supplement or replace vaginal smears was briefly described above. The procedure, based on a simple suction-aspiration of the endometrium via a small caliber metal cannula attached to a syringe, was inexpensive and reasonably well tolerated by the patients. The tiny tissue fragments were processed by the cell block technique. The method, applied to several hundred patients, gave excellent quality of preparations, was rapid, and resulted in a number of important, sometimes unsuspected diagnoses of endometrial carcinoma (Fig. 31-28).

The procedure was not tested on asymptomatic women and, therefore, its value as a detection method of occult endometrial carcinoma is unknown.

SYSTEMATIC SEARCH FOR ENDOMETRIAL CARCINOMA AND HYPERPLASIA IN ASYMPTOMATIC WOMEN

Under a contract with the National Cancer Institute, USA, a major program of endometrial cancer detection was undertaken by the writer and his colleagues between January 1979 and

June 1982 (Koss et al, 1981, 1984). The purposes of the program were as follows:

- To determine by direct endometrial sampling and conventional cytologic methods whether occult endometrial carcinoma is a detectable disease in asymptomatic women age 45 and above
- To identify the optimal methods of screening for occult endometrial carcinoma
- To determine the prevalence and incidence of occult endometrial carcinoma and hyperplasia and the relationship of these entities to each other
- To identify, by epidemiologic study, high-risk groups to facilitate future screening efforts

The patients were recruited to this study by advertising, visits to local churches and temples, and talks to groups of women. The services were offered free of charge. The conditions of acceptance to the project were age 45 or older, intact uterus, no history or evidence of abnormal vaginal bleeding or spotting, and the willingness to sign an informed consent after explanation of the procedure. To satisfy the epidemiologic aspects of this study, a detailed questionnaire, pertaining to the pertinent medical history, was obtained on each examinee by a trained social worker. Each woman's weight, height, and blood pressure were measured before gynecologic examination and breast palpation, also a part of the services offered to the volunteers.

In all, 2,586 women were enrolled in the study, each receiving a full initial examination; of these, 1,567 women were examined for a second time 1 year later, and 187 were screened for a third time, two years after the initial examination.

P.457

The age distribution of the primary examinees and the returnees is shown in Table 13-4. It may be noted that the cohort included 2.3% of women between the ages of 40 and 45 who could not be excluded from the study for social reasons.

TABLE 13-2 HISTOLOGIC LESIONS IN CARCINOMA OF THE ENDOMETRIUM

	In Situ Adenocarcinoma	Adenocarcinoma with Only Superficial Invasion of Myometrium	Advanced Adenocarcinoma	Radiation Prior to Hysterectomy		Diagnosis on Biopsy, Curettage, or Submitted Slide Only
				No Residual Cancer	Residual Cancer	
Asymptomatic (22 cases) 100%	7 (31.8%)	5	2*	3	2	3
Slight symptoms (17 cases)† 100%	2 (12%)	4	4‡	3	1	3
Symptomatic (63 cases) 100%	4 (0.6%)§	16	26	3	3	11

* Histologic diagnosis and treatment delayed 4 years in 1 case.

† Carcinoma suspected clinically in 5 cases only.

§ In 2 cases also polyps and hyperplasia.

(Koss LG, Durfee GR. Cytologic diagnosis of endometrial carcinoma. Result of ten years of experience. Acta Cytol 6:519-531, 1962.)

At the time of the initiation of this project, there were two promising commercially available endometrial sampling devices: the Mi-Mark and the Isaacs' instruments. The Mi-Mark, invented by Milan and Markley, was a two-part plastic instrument, comprising a uterine sound and a helical sampling spatula, 3.5 mm in diameter. The Isaacs' instrument consisted of a malleable, perforated metal suction cannula, 2 mm in diameter, provided with an adjustable cervical obturator and attached to a syringe. The instruments were assigned by a computer program to insure random distribution. Either instrument could be introduced into the uterine cavity of about 93% of asymptomatic examinees without anesthesia, although the success rate was somewhat higher and the level of discomfort less with the Isaacs' instrument because of its smaller diameter. The method of processing by direct smears and by cell blocks is shown in Figure 13-20. Besides the direct endometrial sampling, each woman received a lateral scrape smear of the vaginal wall (to determine the level of maturation of squamous cells), a vaginal pool smear, and a cervical scrape and cotton swab smears. An endocervical aspiration smear, obtained by means of a commercially available device, proved quite useless and was discontinued after the first 1,000 examinations.

TABLE 13-3 AVERAGE AGE OF PATIENTS WITH ENDOMETRIAL CARCINOMAS

Asymptomatic (22 patients)	Slight Symptoms (17 patients)	Symptomatic Patients (63 patients)
52.0 years	56.5 years	58.1 years

(Koss LG, Durfee GR. Cytologic diagnosis of endometrial carcinoma: Result of ten years of experience. Acta Cytol 6:519-531, 1962.)

The study yielded a number of important observations, summarized in several prior publications (Koss et al, 1981, 1984). The study has, so far, been unique, has not been duplicated, and may serve as a model for future studies of this type. For this reason, the key results of this study are reported.

Age at Onset of Menopause

There were 2,061 postmenopausal women enrolled in the study. As shown in Table 13-5, the study revealed that the **normal American woman may menstruate to the age of 55 years**. A small group of women is apparently capable of normal menstruation to the age of 59 (3% of the sample). There was epidemiologic evidence that the late menstruating women were at an increased risk for endometrial carcinoma (see below). The same table also shows other data of significance in the epidemiologic study (see below).

Occult Endometrial Carcinoma

Table 13-6 shows the prevalence and incidence of endometrial carcinomas in this cohort of women. The **prevalence** was defined as all cancers diagnosed on the first screening or coming to light within one year after the first screening. The **incidence**, expressed in women years, included all cancers

diagnosed on the second or third screening or coming to light thereafter. The term, **women-years**, indicates the likelihood of developing a disease process calculated per 1,000 years of women's life, following an episode, in this case, 1 year after the first screening.

P.458

TABLE 13-4 AGE DISTRIBUTION OF 2,586 PRIMARY EXAMINEES AND 1,567 RETURNEES

Age	Primary Examinees		Returnees	
	Number of Patients	Percentage of Sample	Number of Patients	Percentage of Samples
40-44	61	2.36	8	0.51
45-49	532	20.57	277	17.68
50-54	574	22.19	384	24.51
55-59	535	20.69	338	21.57
60-64	388	15.00	229	14.61
65-69	248	9.59	173	11.04
70-74	167	6.46	101	6.45
75-79	64	2.47	41	2.62
80-90	17	0.66	16	1.02
Total	2,586	100.00	1,567	100.00

(Koss LG, et al. Detection of endometrial carcinoma and hyperplasia in asymptomatic women. Obstet Gynecol 64:1-11, 1984.)

There were 16 endometrial carcinomas discovered on first screening and two missed on screening and observed in women who became symptomatic within the 12 months following the first screening, for a **prevalence rate of 7 in 1,000**. Another carcinoma was diagnosed on the second screening; two additional cancers, missed on screening, were observed after the second screening in women who became symptomatic, for an **incidence rate of 1.7 per 1,000 women years**.

TABLE 13-5 EPIDEMIOLOGIC PROFILE OF 2,586 PRIMARY EXAMINEES

	No. of Women	Percentage
Age at Onset of Menopause		

39 or younger	43	2.90
40-44	138	6.70

† One with carcinoma of left ovary, metastatic or primary.

‡ On estrogen therapy of long duration.
(Koss LG, et al. Detection of endometrial carcinoma and hyperplasia in asymptomatic women. Obstet Gynecol 64:1-11, 1984; with permission.)

Occult Endometrial Hyperplasia

As shown in Table 13-6, the **rate of occult hyperplasias, including endometrial polyps, was approximately equal to the rate of occult carcinomas**. There may be some minor bias in the study, inasmuch as symptomatic women (hence, possibly including those with hyperplasia) were excluded. However, no more than three women were excluded from the study and referred for further care because of a history of symptoms; thus the rate of endometrial hyperplasias was exceedingly low. On the assumption, based on studies of Gusberg and Kaplan (1963), that about 10% of hyperplasias become associated with cancer, the observed rate of hyperplasias was much below the expected rate, casting serious doubts on the relationship of hyperplasia to endometrial cancer. In the 12 hysterectomy specimens from patients with endometrial carcinoma, examined without prior radiotherapy (see Table 13-7), focal hyperplasia was present in five and extensive hyperplasia was found in only one uterus, in a woman receiving long-term estrogen therapy. In six uteri, there was no evidence of hyperplasia adjacent to carcinoma.

Risk Factors

Obesity

Because obesity is classically considered a risk factor in endometrial carcinoma, the status of our examinees was determined by an index of obesity, known as the **Quetelet index**. This index takes into account, not only the weight, but also the height of the person, by a formula shown in Figure 13-29. The distribution of the Quetelet index and the distribution of 21 endometrial carcinomas within the Quetelet groups are also shown in this figure, taking into account the history of estrogen therapy. It may be noted that **endometrial carcinomas in women receiving estrogen therapy occurred more often in the group of slender women** with low Quetelet indices; although the difference was below statistical significance, it showed an interesting trend, discussed above.

Other Risk Factors

A statistical evaluation of risk factors in occult endometrial carcinoma, performed by Dr. Martin Lesser, is shown in Table 13-8. Among the several factors listed, only one, namely **late onset of menopause**, proved to be statistically valid. In other words, women whose menstrual activity ceases before the age of 50 appear to be protected from endometrial cancer. **Diabetes**, classically considered a risk factor for endometrial carcinoma, did not prove to be so in this study. **Hormonal level**, as determined by maturation of squamous cells in scrape smears of the lateral vaginal wall, **was not helpful in this study**. Contrary to the prior observations suggesting that a high level of maturation of squamous cells was a common event in the vaginal pool smears of patients with occult endometrial carcinoma (see above), this was not the case in this cohort of patients. The 17 postmenopausal patients with endometrial carcinoma had, for the most part, a pattern of postmenopausal atrophy.

Thus, this study failed to reveal a specific high-risk group of women who should be selected for screening for occult endometrial cancer. Although menopause delayed past the

P.460

age of 50 appeared to be a risk factor, this event was observed in nearly 80% of our population (see Table 13-4).

Figure 13-29 Distribution of 21 occult endometrial carcinomas according to Quetelet (obesity) index, calculated for a screened population of 2,579 women (data on seven women were not available).

The Performance of Sampling Methods in the Discovery of Occult Endometrial Carcinoma

Direct endometrial smears, the cell blocks of direct endometrial samples, and the vaginal smears contributed to the discovery of 17 cases of occult endometrial carcinoma. Direct endometrial sampling proved to be the most efficacious part of the diagnostic system, having established the diagnosis in 16 cases. In one case, the endometrial smear alone was positive and, in one case, only the cell block. In the remaining 14 cases, both the endometrial smear and the cell block showed evidence of disease. In the 17th case, a 71-year-old woman with cervical stenosis preventing endometrial sampling, the vaginal pool smear was positive. This patient had a deeply infiltrating stage IA carcinoma.

P.461

It is of interest that, in four other patients, the vaginal pool smears also showed evidence of endometrial carcinoma. In all, 5 of the 17 occult carcinomas (or nearly one-third of the cases) could have been diagnosed by vaginal smear alone.

TABLE 13-8 ASSESSMENT OF RISK FACTORS IN 2,579 WOMEN

Factor	No. of Women	No. of Carcinomas	Rate/1,000	Odds Ratio	P Value
Race					
White	2,031	18	8.8	1.65:1	NS

* *P* value, Mantel-Haenszel test; for “onset of menopause” Mantel's extension procedure.

NS = not significant. Risk factors for diabetes and hypertension (not shown) were NS. (Koss LG, et al. Detection of endometrial carcinoma and hyperplasia in asymptomatic women. *Obstet Gynecol* 64:1-11, 1984; with permission.)

Other Findings

There were several unanticipated incidental findings in the study: there were **two cases of ovarian carcinoma and one case of tubal carcinoma**. One ovarian cancer was recognized in an endometrial smear and was initially mistaken for an endometrial carcinoma. The other ovarian cancer was observed in a vaginal pool smear. The tubal carcinoma was observed in the endometrial sampling and in the vaginal pool smear.

There were also 22 cases of **cervical intraepithelial neoplasia, including three classical carcinomas in situ** recognized in the screened population, all suggesting that the postmenopausal women do not receive the proper gynecologic care that they deserve. There were also **four mammary carcinomas** identified by palpation of the breasts, a part of the examination offered in this study.

It is our belief that the study offered **new vistas on the need for care for the postmenopausal woman**. It is regrettable that the study had to be discontinued after 4 years for lack of funding.

Other Studies

Currently, some attempts are in progress to perform endometrial sampling on asymptomatic women by the **Tao brush** (Maksem, 2000). The results of this study, conducted on 113

patients, although not correlated with clinical data, suggest that the method may be successfully used in the diagnosis of occult cancers of the endometrium.

Rare lesions of the endometrium are discussed in Chapter 17.

Diseases of the Vagina, Vulva, Perineum, and Anus

THE VAGINA

Normal Cytology

Except for the mucus-secreting Bartholin's glands, discussed below, the vagina is lined by squamous epithelium that is identical to that lining the outer surface of the uterine cervix. Normal cytology consists of squamous cells and their variants, identical to those described in Chapter 8.

Benign Abnormalities

Inflammatory Disorders

The inflammatory disorders and their causes, observed in the vagina, are generally the same as in the uterine cervix (see Chap. 10). **Ulceration of the vaginal epithelium** may occur under a variety of circumstances, such as the presence of a pessary. Wilbur et al (1993) described vaginal ulcers in a rare disorder of unknown etiology, **the Behçet's disease**. In the case described, **abnormal squamous cells, mimicking cancer**, were observed in cervicovaginal smears. Cases of **malakoplakia** of the vagina were reported by Lin et al (1979) and by Chalvardjian et al (1985). For further discussion of this rare disorder, see Chapter 22.

Melanosis of vagina, i.e., accumulation of melanin in the epithelium, is a very uncommon benign condition that may mimic a malignant melanoma (Karney et al, 2001). Malignant melanoma is discussed in Chapter 17.

Infections and Hormonal Status

The responses of the vaginal squamous epithelium to events in the normal menstrual cycle and under the impact of hormonal medication are discussed in Chapters 8 and 9. The susceptibility of the vagina to infectious agents depends on the hormonal status of the squamous epithelial lining: **absence of epithelial maturation before puberty and after the menopause favors the proliferation of infectious agents** (see Chap. 10).

Posthysterectomy Glandular Cells

Glandular cells **of endocervical type have been observed in vaginal smears after hysterectomy** (Bewtra, 1992; Tambouret et al, 1998). The origin of these cells is not clear but the authors postulated **focal glandular metaplasia** or **adenosis**, occurring in the vaginal epithelium after treatment by radiotherapy or 5-fluorouracil (for further discussion of vaginal adenosis, see below.)

Fistulous Tracts

Fistulous tracts between the vagina and an adjacent organ, such as **the rectum (recto-vaginal fistula)**, or **the bladder (vesicovaginal fistula)**, may result in the presence of epithelial cells of urothelial or intestinal origin in vaginal smears.
